**Fig 23.79** — K0OV uses this mobile setup for RDF on several bands, with separate antennas for each band that mate with a common lower mast section, pointer and 360° indicator. Antenna shown is a heavy gauge wire quad for 2 m.

range, at the expense of increased weight and wind resistance. It can get mashed going under a willow, but it is easily reshaped and returned to service.

Yagis are a close second to quads in popularity. Commercial models work fine for VHF RDF, provided that the mast is attached at a good balance point. Lightweight and small-diameter elements are desirable for ease of turning at high speeds.

A well-designed mobile Yagi or quad installation includes a method of selecting wave polarization. Although vertical polarization is the norm for VHF-FM communications, horizontal polarization is allowed on many T-hunts. Results will be poor if a VHF RDF antenna is cross-polarized to the transmitting antenna, because multipath and scattered signals (which have indeterminate polarization) are enhanced, relative to the cross-polarized direct signal. The installation of Fig 23.78 features a slip joint at the boom-to-mast junction, with an actuating cord to rotate the boom, changing the polarization. Mechanical stops limit the boom rotation to 90°.

### Parasitic Array Performance for RDF

The directional gain of a mobile beam (typically 8 dB or more) makes it unexcelled for both weak signal competitive hunts and for locating interference such as TV cable leakage. With an appropriate receiver, you can get bearings on any signal mode, including FM, SSB, CW, TV, pulses and noise. Because only the response peak is used, the null-fill problems and proximity effects of loops and phased arrays do not exist.

You can observe multiple directions of arrival while rotating the antenna, allowing you to make educated guesses as to which signal peaks are direct and which are from nondirect paths or scattering. Skilled operators can estimate distance to the transmitter from the rate of signal strength increase with distance traveled. The RDF beam is useful for transmitting, if necessary, but use care not to damage an attenuator in the coax line by transmitting through it.

The 3-dB beamwidth of typical mobile-mount VHF beams is on the order of 80°. This is a great improvement over 2-element driven arrays, but it is still not possible to get pinpoint bearing accuracy. You can achieve errors of less than 10° by carefully reading the S-meter. In practice, this is not a major hindrance to successful mobile RDF. Mobile users are not as concerned with precise bearings as fixed station operators, because mobile readings are used primarily to give the general di-

rection of travel to “home in” on the signal. Mobile bearings are continuously updated from new, closer locations.

Amplitude-based RDF may be very difficult when signal level varies rapidly. The transmitter hider may be changing power, or the target antenna may be moving or near a well-traveled road or airport. The resultant rapid S-meter movement makes it hard to take accurate bearings with a quad. The process is slow because the antenna must be carefully rotated by hand to “eyeball average” the meter readings.

### Switched Antenna RDF Units

Three popular types of RDF systems are relatively insensitive to variations in signal level. Two of them use a pair of vertical dipole antennas, spaced  $\frac{1}{2} \lambda$  or less apart, and alternately switched at a rapid rate to the input of the receiver. In use, the indications of the two systems are similar, but the principles are different.

#### Switched Pattern Systems

The switched pattern RDF set (Fig 23.80) alternately creates two cardioid antenna patterns with lobes to the left and the right. The patterns are generated in much the same way as in the phased arrays described above. PIN RF diodes select the alternating patterns. The combined antenna outputs go to a receiver with AM detection. Processing after the detector output determines the phase or amplitude difference between the patterns' responses to the signal.

Switched pattern RDF sets typically have a zero center meter as an indicator. The meter swings negative when the signal is coming from the user's left, and positive when the signal source is on the right. When the plane of the an-

tenna is exactly perpendicular to the direction of the signal source, the meter reads zero.

The sharpness of the zero crossing indication makes possible more precise bearings than those obtainable with a quad or Yagi. Under ideal conditions with a well-built unit, null direction accuracy is within 1°. Meter deflection tells the user which way to turn to zero the meter. For example, a negative (left) reading requires turning the antenna left. This solves the 180° ambiguity caused by the two zero crossings in each complete rotation of the antenna system.

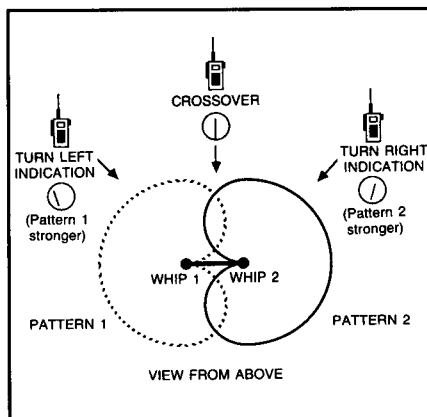

Because it requires AM detection of the switched pattern signal, this RDF system finds its greatest use in the 120-MHz aircraft band, where AM is the standard mode. Commercial manufacturers make portable RDF sets with switched pattern antennas and built-in receivers for field portable use. These sets can usually be adapted to the amateur 144-MHz band. Other designs are adaptable to any VHF receiver that covers the frequency of interest and has an AM detector built in or added.

Switched pattern units work well for RDF from small aircraft, for which the two vertical antennas are mounted in fixed positions on the outside of the fuselage or simply taped inside the windshield. The left-right indication tells the pilot which way to turn the aircraft to home in. Since street vehicles generally travel only on roads, fixed mounting of the antennas on them is undesirable. Mounting vehicular switched-pattern arrays on a rotatable mast is best.

#### Time of Arrival Systems

Another kind of switched antenna RDF set uses the difference in arrival times of the signal wavefront at the two antennas. This narrow-aperture Time-Difference-of-Arrival (TDOA) technology is used for many sophisticated military RDF systems. The rudimentary TDOA implementation of Fig 23.81 is quite effective for amateur use. The signal from transmitter 1 reaches antenna A before antenna B. Conversely, the signal from transmitter 3 reaches antenna B before antenna A. When the plane of the antenna is perpendicular to the signal source (as transmitter 2 is in the figure), the signal arrives at both antennas simultaneously.

If the outputs of the antennas are alternately switched at an audio rate to the receiver input, the differences in the arrival times of a continuous signal produce phase changes that are detected by an FM discriminator. The resulting short pulses sound like a tone in the receiver output.

**Fig 23.80** — In a switched pattern RDF set, the responses of two cardioid antenna patterns are summed to drive a zero center indicator.

**Fig 23.81** — A dual-antenna TDOA RDF system has a similar indicator to a switched pattern unit, but it obtains bearings by determining which of its antennas is closer to the transmitter.

The tone disappears when the antennas are equidistant from the signal source, giving an audible null.

The polarity of the pulses at the discriminator output is a function of which antenna is closer to the source. Therefore, the pulses can be processed and used to drive a left-right zero center meter in a manner similar to the switched pattern units described above. Left-right LED indicators may replace the meter for economy and visibility at night.

RDF operations with a TDOA dual antenna RDF are done in the same manner as with a switched antenna RDF set. The main difference is the requirement for an FM receiver in the TDOA system and an AM receiver in the switched pattern case. No RF attenuator is needed for close-in work in the TDOA case.

Popular designs for practical do-it-yourself TDOA RDF sets include the Simple Seeker (described elsewhere in this chapter) and the W9DUU design (see article by Bohrer in the Bibliography). Articles with plans for the Handy Tracker, a simple TDOA set with a delay line to resolve the dual-null ambiguity instead of LEDs or a meter, are listed in the Bibliography.

### Performance Comparison

Both types of dual antenna RDFs make good on-foot "sniffing" devices and are excellent performers when there are rapid amplitude variations in the incoming signal. They are the units of choice for airborne work. Compared to Yagis and quads, they give good directional performance over a much wider frequency range. Their indications are more precise than those of beams with broad forward lobes.

Dual-antenna RDF sets frequently give

inaccurate bearings in multipath situations, because they cannot resolve signals of nearly equal levels from more than one direction. Because multipath signals are a combined pattern of peaks and nulls, they appear to change in amplitude and bearing as you move the RDF antenna along the bearing path or perpendicular to it, whereas a non-multipath signal will have constant strength and bearing.

The best way to overcome this problem is to take large numbers of bearings while moving toward the transmitter. Taking bearings while in motion averages out the effects of multipath, making the direct signal more readily discernible. Some TDOA RDF sets have a slow-response mode that aids the averaging process.

Switched antenna systems generally do not perform well when the incoming signal is horizontally polarized. In such cases, the bearings may be inaccurate or unreadable. TDOA units require a carrier type signal such as FM or CW; they usually cannot yield bearings on noise or pulse signals.

Unless an additional method is employed to measure signal strength, it is easy to "overshoot" the hidden transmitter location with a TDOA set. It is not uncommon to see a TDOA foxhunter walk over the top of a concealed transmitter and walk away, following the opposite 180° null, because there is no display of signal amplitude.

### Doppler RDF Sets

RDF sets using the Doppler principle are popular in many areas because of their ease of use. They have an indicator that instantaneously displays direction of the signal source relative to the vehicle heading, either on a circular ring of LEDs or a digital readout in degrees. A ring of four, eight or more antennas picks up the signal. Quarter-wavelength monopoles on a ground plane are popular for vehicle use, but half-wavelength vertical dipoles, where practical, perform better.

Radio signals received on a rapidly moving antenna experience a frequency shift due to the Doppler effect, a phenomenon well known to anyone who has observed a moving car with its horn sounding. The horn's pitch appears higher than normal as the car approaches, and lower as the car recedes. Similarly, the received radio frequency increases as the antenna moves toward the transmitter and vice versa. An FM receiver will detect this frequency change.

**Fig 23.82** shows a  $\frac{1}{4}\lambda$  vertical antenna being moved on a circular track around point P, with constant angular velocity. As the antenna approaches the transmitter on

**Fig 23.82** — A theoretical Doppler antenna circles around point P, continuously moving toward and away from the source at an audio rate.

**Fig 23.83** — Frequency shift versus time produced by the rotating antenna movement toward and away from the signal source.

its track, the received frequency is shifted higher. The highest instantaneous frequency occurs when the antenna is at point A, because tangential velocity toward the transmitter is maximum at that point. Conversely, the lowest frequency occurs when the antenna reaches point C, where velocity is maximum away from the transmitter.

**Fig 23.83** shows a plot of the component of the tangential velocity that is in the direction of the transmitter as the antenna moves around the circle. Comparing Figs 23.82 and 23.83, notice that at B in Fig 23.83, the tangential velocity is crossing zero from the positive to the negative and the antenna is closest to the transmitter. The Doppler shift and resulting audio output from the receiver discriminator follow the same plot, so that a negative-slope zero-crossing detector, synchronized with the antenna rotation, senses the incoming direction of the signal.

The amount of frequency shift due to the Doppler effect is proportional to the RF frequency and the tangential antenna velocity. The velocity is a function of the radius of rotation and the angular velocity (rotation rate). The radius of rotation must be less than  $\frac{1}{4}\lambda$  to avoid errors. To get a usable amount of FM deviation (comparable to typical voice modulation) with

this radius, the antenna must rotate at approximately 30,000 RPM (500 Hz). This puts the Doppler tone in the audio range for easy processing.

Mechanically rotating a whip antenna at this rate is impractical, but a ring of whips, switched to the receiver in succession with RF PIN diodes, can simulate a rapidly rotating antenna. Doppler RDF sets must be used with receivers having FM detectors. The DoppleScAnt and Roanoke Doppler (see Bibliography) are mobile Doppler RDF sets designed for inexpensive home construction.

### **Doppler Advantages and Disadvantages**

Ring-antenna Doppler sets are the ultimate in simplicity of operation for mobile RDF. There are no moving parts and no manual antenna pointing. Rapid direction indications are displayed on very short signal bursts.

Many units lock in the displayed direction after the signal leaves the air. Power variations in the source signal cause no difficulties, as long as the signal remains above the RDF detection threshold. A Doppler antenna goes on top of any car quickly, with no holes to drill. Many Local Interference Committee members choose Dopplers for tracking malicious interference, because they are inconspicuous (compared to beams) and effective at tracking the strong vertically polarized signals that repeater jammers usually emit.

A Doppler does not provide superior performance in all VHF RDF situations. If the signal is too weak for detection by the Doppler unit, the hunt advantage goes to teams with beams. Doppler installations are not suitable for on-foot sniffing. The limitations of other switched antenna RDFs also apply: (1) poor results with horizontally polarized signals, (2) no indication of distance, (3) carrier type signals only and (4) inadvisability of transmitting through the antenna.

Readout to the nearest degree is provided on some commercial Doppler units. This does not guarantee that level of accuracy, however. A well-designed four-monopole set is typically capable of  $\pm 5^\circ$  accuracy on 2 m, if the target signal is vertically polarized and there are no multipath effects.

The rapid antenna switching can introduce cross modulation products when the user is near strong off-channel RF sources. This self-generated interference can temporarily render the system unusable. While not a common problem with mobile Dopplers, it makes the Doppler a poor choice for use in remote RDF installations at fixed sites with high power VHF transmitters nearby.

### **Mobile RDF System Installation**

Of these mobile VHF RDF systems, the Doppler type is clearly the simplest from a mechanical installation standpoint. A four-whip Doppler RDF array is easy to implement with magnetic mount antennas. Alternately, you can mount all the whips on a frame that attaches to the vehicle roof with suction cups. In either case, setup is

**Fig 23.84 — A set of TD0A RDF antennas is light weight and mounts readily through a sedan window without excessive overhang.**

**Fig 23.85 — A window box allows the navigator to turn a mast mounted antenna with ease while remaining dry and warm. No holes in the vehicle are needed with a properly designed window box.**

rapid and requires no holes in the vehicle.

You can turn small VHF beams and dual-antenna arrays readily by extending the mast through a window. Installation on each model vehicle is different, but usually the mast can be held in place with some sort of cup in the arm rest and a plastic tie at the top of the window, as in **Fig 23.84**. This technique works best on cars with frames around the windows, which allow the door to be opened with the antenna in place. Check local vehicle codes, which limit how far your antenna may protrude beyond the line of the fenders. Larger antennas may have to be put on the passenger side of the vehicle, where greater overhang is generally permissible.

The window box (**Fig 23.85**) is an improvement over through-the-window mounts. It provides a solid, easy-turning mount for the mast. The plastic panel keeps out bad weather. You will need to custom-design the box for your vehicle model. Vehicle codes may limit the use of a window box to the passenger side.

For the ultimate in convenience and versatility, cast your fears aside, drill a hole through the center of the roof and install a waterproof bushing. A roof-hole mount permits the use of large antennas without overhang violations. The driver, front passenger and even a rear passenger can turn the mast when required. The installation in **Fig 23.79** uses a roof-hole bushing made from mating threaded PVC pipe adapters and reducers. When it is not in use for RDF, a PVC pipe cap provides a watertight cover. There is a pointer and 360° indicator at the bottom of the mast for precise bearings.

### **DIRECTION-FINDING TECHNIQUES AND PROJECTS**

The ability to locate a transmitter quickly with RDF techniques is a skill you will acquire only with practice. It is very important to become familiar with your equipment and its limitations. You must also understand how radio signals behave in different types of terrain at the frequency of the hunt. Experience is the best teacher, but reading and hearing the stories of others who are active in RDF will help you get started.

Verify proper performance of your portable RDF system before you attempt to track signals in unknown locations. Of primary concern is the accuracy and symmetry of the antenna pattern. For instance, a lopsided figure-8 pattern with a loop, Adcock, or TD0A set leads to large bearing errors. Nulls should be exactly 180° apart and exactly at right angles to the loop plane or the array boom. Similarly, if feed-line pickup causes an off-axis main lobe in your VHF

RDF beam, your route to the target will be a spiral instead of a straight line.

Perform initial checkout with a low-powered test transmitter at a distance of a few hundred feet. Compare the RDF bearing indication with the visual path to the transmitter. Try to "find" the transmitter with the RDF equipment as if its position were not known. Be sure to check all nulls on antennas that have more than one.

If imbalance or off-axis response is found in the antennas, there are two options available. One is to correct it, insofar as possible. A second option is to accept it and use some kind of indicator or correction procedure to show the true directions of signals. Sometimes the end result of the calibration procedure is a compromise between these two options, as a perfect pattern may be difficult or impossible to attain.

The same calibration suggestions apply for fixed RDF installations, such as a base station HF Adcock or VHF beam. Of course it does no good to move it to an open field. Instead, calibrate the array in its intended operating position, using a portable or mobile transmitter. Because of nearby obstructions or reflecting objects, your antenna may not indicate the precise direction of the transmitter. Check for imbalance and systemic error by taking readings with the test emitter at locations in several different directions.

The test signal should be at a distance of 2 or 3 miles for these measurements, and should be in as clear an area as possible during transmissions. Avoid locations where power lines and other overhead wiring can conduct signal from the transmitter to the RDF site. Once antenna adjustments are optimized, make a table of bearing errors noted in all compass directions. Apply these error values as corrections when actual measurements are made.

### Preparing to Hunt

Successfully tracking down a hidden transmitter involves detective work — examining all the clues, weighing the evidence and using good judgment. Before setting out to locate the source of a signal, note its general characteristics. Is the frequency constant, or does it drift? Is the signal continuous, and if not, how long are transmissions? Do transmissions occur at regular intervals, or are they sporadic? Irregular, intermittent signals are the most difficult to locate, requiring patience and quick action to get bearings when the transmitter comes on.

### Refraction, Reflections and the Night Effect

You will get best accuracy in tracking ground wave signals when the propaga-

tion path is over homogeneous terrain. If there is a land/water boundary in the path, the different conductivities of the two media can cause bending (refraction) of the wave front, as in Fig 23.86A. Even the most sophisticated RDF equipment will not indicate the correct bearing in this situation, as the equipment can only show the direction from which the signal is arriving. RDFers have observed this phenomenon on both HF and VHF bands.

Signal reflections also cause misleading bearings. This effect becomes more pronounced as frequency increases. T-hunters regularly achieve strong signal bounces from distant mountain ranges on the 144-MHz band.

Tall buildings also reflect VHF/UHF signals, making midcity RDF difficult. Hunting on the 440-MHz and higher amateur bands is even more arduous because of the plethora of reflecting objects.

In areas of signal reflection and multipath, some RDF gear may indicate that the signal is coming from an intermediate point, as in Fig 23.86B. High gain VHF/UHF RDF beams will show direct and reflected signals as separate S-meter peaks, leaving it to the operator to determine which is which. Null-based RDF antennas, such as phased arrays and loops, have the most difficulty with multipath, because the multiple signals tend to make the nulls very shallow or fill them in entirely, resulting in no bearing indication at all.

If the direct path to the transmitter is masked by intervening terrain, a signal

reflection from a higher mountain, building, water tower, or the like may be much stronger than the direct signal. In extreme cases, triangulation from several locations will appear to "confirm" that the transmitter is at the location of the reflecting object. The direct signal may not be detectable until you arrive at the reflecting point or another high location.

Objects near the observer such as concrete/steel buildings, power lines and chain-link fences will distort the incoming wavefront and give bearing errors. Even a dense grove of trees can sometimes have an adverse effect. It is always best to take readings in locations that are as open and clear as possible, and to take bearings from numerous positions for confirmation. Testing of RDF gear should also be done in clear locations.

Locating local signal sources on frequencies below 10 MHz is much easier during daylight hours, particularly with loop antennas. In the daytime, D-layer absorption minimizes skywave propagation on these frequencies. When the D layer disappears after sundown, you may hear the signal by a combination of ground wave and high-angle skywave, making it difficult or impossible to obtain a bearing. RDFers call this phenomenon the *night effect*.

While some mobile T-hunters prefer to go it alone, most have more success by teaming up and assigning tasks. The driver concentrates on handling the vehicle, while the assistant (called the "navigator" by some teams) turns the beam, reads

Fig 23.86 — RDF errors caused by refraction (A) and reflection (B). The reading at A is false because the signal actually arrives from a direction that is different from that to the source. At B, a direct signal from the source combines with a reflected signal from the mountain ridge. The RDF set may average the signals as shown, or indicate two lines of bearing.

the meters and calls out bearings. The assistant is also responsible for maps and plotting, unless there is a third team member for that task.

### Maps and Bearing-Measurements

Possessing accurate maps and knowing how to use them is very important for successful RDF. Even in difficult situations where precise bearings cannot be obtained, a town or city map will help in plotting points where signal levels are high and low. For example, power line noise tends to propagate along the power line and radiates as it does so. Instead of a single source, the noise appears to come from a multitude of sources. This renders many ordinary RDF techniques ineffective. Mapping locations where signal amplitudes are highest will help pinpoint the source.

Several types of area-wide maps are suitable for navigation and triangulation. Street and highway maps work well for mobile work. Large detailed maps are preferable to thick map books. Contour maps are ideal for open country. Aeronautical charts are also suitable. Good sources of maps include auto clubs, stores catering to camping/hunting enthusiasts and city/county engineering departments.

A *heading* is a reading in degrees relative to some external reference, such as your house or vehicle; a *bearing* is the

target signal's direction relative to your position. Plotting a bearing on a hidden transmitter from your vehicle requires that you know the vehicle location, transmitter heading with respect to the vehicle and vehicle heading with respect to true north.

First, determine your location, using landmarks or a navigation device such as a loran or GPS receiver. Next, using your RDF equipment, determine the bearing to the hidden transmitter (0 to 359.9°) with respect to the vehicle. Zero degrees heading corresponds to signals coming from directly in front of the vehicle, signals from the right indicate 90°, and so on.

Finally, determine your vehicle's true heading, that is, its heading relative to true north. Compass needles point to magnetic north and yield magnetic headings. Translating a magnetic heading into a true heading requires adding a correction factor, called *magnetic declination*, which is a positive or negative factor that depends on your location.

Declination for your area is given on US Geological Survey (USGS) maps, though it undergoes long-term changes. Add the declination to your magnetic heading to get a true heading.

As an example, assume that the transmitted signal arrives at 30° with respect to the vehicle heading, that the compass in-

dicates that the vehicle's heading is 15°, and the magnetic declination is +15°. Add these values to get a true transmitter bearing (that is, a bearing with respect to true north) of 60°.

Because of the large mass of surrounding metal, it is very difficult to calibrate an in-car compass for high accuracy at all vehicle headings. It is better to use a remotely mounted flux-gate compass sensor, properly corrected, to get vehicle headings, or to stop and use a hand compass to measure the vehicle heading from the outside. If you T-hunt with a mobile VHF beam or quad, you can use your manual compass to sight along the antenna boom for a magnetic bearing, then add the declination for true bearing to the fox.

### Triangulation Techniques

If you can obtain accurate bearings from two locations separated by a suitable distance, the technique of *triangulation* will give the expected location of the transmitter. The intersection of the lines of bearing from each location provides a *fix*. Triangulation accuracy is greatest when stations are located such that their bearings intersect at right angles. Accuracy is poor when the angle between bearings approaches 0° or 180°.

There is always uncertainty in the fixes obtained by triangulation due to equipment limitations, propagation effects and measurement errors. Obtaining bearings from three or more locations reduces the uncertainty. A good way to show the probable area of the transmitter on the triangulation map is to draw bearings as a narrow sector instead of as a single line. Sector width represents the amount of bearing uncertainty. **Fig 23.87** shows a portion of a map marked in this manner. Note how the bearing from Site 3 has narrowed down the probable area of the transmitter position.

### Computerized Transmitter Hunting

A portable computer is an excellent tool for streamlining the RDF process. Some T-hunters use one to optimize VHF beam bearings, generating a two-dimensional plot of signal strength versus azimuth. Others have automated the bearing-taking process by using a computer to capture signal headings from a Doppler RDF set, vehicle heading from a flux-gate compass, and vehicle location from a GPS receiver (**Fig 23.88**). The computer program can compute averaged headings from a Doppler set to reduce multipath effects.

Provided with perfect position and bearing information, computer triangulation could determine the transmitter location within the limits of its computational ac-

**Fig 23.87** — Bearing sectors from three RDF positions drawn on a map for triangulation. In this case, bearings are from loop antennas, which have 180° ambiguity.

curacy. Two bearings would exactly locate a fox. Of course, there are always uncertainties and inaccuracies in bearing and position data. If these uncertainties can be determined, the program can compute the uncertainty of the triangulated bearings. A "smart" computer program can evaluate bearings, triangulate the bearings of multiple hunters, discard those that appear erroneous, determine which locations have particularly great or small multipath problems and even "grade" the performance of RDF stations.

By adding packet radio connections to a group of computerized base and mobile RDF stations, the processed bearing data from each can be shared. Each station in the network can display the triangulated bearings of all. This requires a common map coordinate set among all stations. The USGS Universal Transverse Mercator (UTM) grid, consisting of 1×1-km grid squares, is a good choice.

The computer is an excellent RDF tool, but it is no substitute for a skilled "navigator." You will probably discover that using a computer on a high-speed T-hunt requires a full-time operator in the vehicle to make full use of its capabilities.

### Skywave Bearings and Triangulation

Many factors make it difficult to obtain accuracy in skywave RDF work. Because of Faraday rotation during propagation, skywave signals are received with random polarization. Sometimes the vertical component is stronger, and at other times the horizontal. During periods when the vertical component is weak, the signal may appear to fade on an Adcock RDF system. At these times, determining an accurate signal null direction becomes very hard.

For a variety of reasons, HF bearing accuracy to within 1 or 2° is the exception rather than the rule. Errors of 3 to 5° are common. An error of 3° at a thousand miles represents a distance of 52 miles. Even with every precaution taken in measurement, do not expect cross-country HF triangulation to pinpoint a signal beyond a county, a corner of a state or a large metropolitan area. The best you can expect is to be able to determine where a mobile RDF group should begin making a local search.

Triangulation mapping with skywave signals is more complex than with ground or direct waves because the expected paths are great-circle routes. Commonly available world maps are not suitable, because the triangulation lines on them must be curved, rather than straight. In general, for flat maps, the larger the area encompassed, the greater the error that straight line triangulation procedures will give.

**Fig 23.88 — Screen plot from a computerized RDF system showing three T-hunt bearings (straight lines radiating from small circles) and the vehicle path (jagged trace). The grid squares correspond to areas of standard topographic maps.**

A highway map is suitable for regional triangulation work if it uses some form of conical projection, such as the Lambert conformal conic system. This maintains the accuracy of angular representation, but the distance scale is not constant over the entire map.

One alternative for worldwide areas is the azimuthal-equidistant projection, better known as a great-circle map. True bearings for great-circle paths are shown as straight lines from the center to all points on the Earth. Maps centered on three or more different RDF sites may be compared to gain an idea of the general geographic area for an unknown source.

For worldwide triangulation, the best projection is the *gnomonic*, on which all great circle paths are represented by straight lines and angular measurements with respect to meridians are true. Gnomonic charts are custom maps prepared especially for government and military agencies.

Skywave signals do not always follow the great-circle path in traveling from a transmitter to a receiver. For example, if the signal is refracted in a tilted layer of the ionosphere, it could arrive from a direction that is several degrees away from the true great-circle bearing.

Another cause of signals arriving off the great-circle path is termed *sidescatter*. It is possible that, at a given time, the ionosphere does not support great-circle propagation of the signal from the transmitter to the receiver because the frequency is above the MUF for that path. However, at the same time, propagation may be supported from both ends of the path to some mutually accessible point off the great-circle path. The signal from the source may

propagate to that point on the Earth's surface and hop in a sideways direction to continue to the receiver.

For example, signals from Central Europe have propagated to New England by hopping from an area in the Atlantic Ocean off the northwest coast of Africa, whereas the great-circle path puts the reflection point off the southern coast of Greenland. Readings in error by as much as 50° or more may result from sidescatter. The effect of propagation disturbances may be that the bearing seems to wander somewhat over a few minutes of time, or it may be weak and fluttery. At other times, however, there may be no telltale signs to indicate that the readings are erroneous.

### Closing In

On a mobile foxhunt, the objective is usually to proceed to the hidden T with minimum time and mileage. Therefore, do not go far out of your way to get off-course bearings just to triangulate. It is usually better to take the shortest route along your initial line of bearing and "home in" on the signal. With a little experience, you will be able to gauge your distance from the fox by noting the amount of attenuation needed to keep the S-meter on scale.

As you approach the transmitter, the signal will become very strong. To keep the S-meter on scale, you will need to add an RF attenuator in the transmission line from the antenna to the receiver. Simple resistive attenuators are discussed in another chapter.

In the final phases of the hunt, you will probably have to leave your mobile and continue the hunt on foot. Even with an attenuator in the line, in the presence of a

## The Thrill of the Hunt

Every weekend, in cities and towns all across the country, hams gather on hilltops for a special kind of contest. In cars, trucks and vans laden with radio gear and bristling with antennas, they anxiously await a faint signal with strange beeps and squawks. After some twisting of antenna masts and a few moments with a map board and protractor . . . they're off!

Somewhere out there, one or more hams have put a transmitter on the air. When the testers start out, they have no idea where they will end up. Usually they do not know what they are looking for. Will the signal source be a car by the road, or a hand-held in the bushes, or something else? Clever hiders have radiated signals from sprinkler pipes, soda cans, baby carriages, shopping carts, survey markers and the ac wiring of a house under construction. Where will it be today?

Good hiders are not content just to see how well they can camouflage their rigs. They delight in finding unusual roads, preferably unmapped. They look for large terrain features to bounce VHF signals, and have employed such exotic antennas as rhombics and helicals to put English on the signal and deceive hunters. Like a ventriloquist, a good hider can make the signal appear to be coming from some other location.

On advanced hunts, the fox may be two states away. No clues are allowed. At the other end of the scale are events just for beginners, with strictly limited boundaries, typically 75 to 2500 square miles. The hider makes short transmissions on a repeater input, taunting the hunters and urging them on. After a while, there are some hints. The goal is to have all hunters arrive in plenty of time for a leisurely picnic or snacks at a nearby restaurant.

Anyone in the family, licensed or not, can join in. It is easy to get your club started in T-hunting—just schedule a hunt and put out the word. Make the first hunt easy, keep the boundaries small, and encourage everyone to come out. After a few starter events, your club will have a solid cadre of regular T-hunters, eager for new challenges. Then, open up the boundaries and increase the level of difficulty.

Give careful thought to how the hunt is scored. The obvious way is to award first place to the first team to find the T. These sprint hunts test your preparation to quickly find jammers or stations in distress. Hunters can start anywhere. But an unlucky traffic break or starting-point choice can mean the difference between winning and losing. Newcomers who are unfamiliar with the territory will be at a disadvantage.

Many hunt groups prefer that all teams start from the same point, usually a hilltop. The winner is determined by lowest elapsed mileage, not the shortest time. This encourages safe driving and careful map reading. Occasionally the last, but most careful, team to find the T wins.

gives the hand-held a cardioid sensitivity pattern, with a sharp decrease in sensitivity to the rear. This null indicates that the source is behind you (Fig 23.89).

If the signal is so strong that you can't find the null, try tuning 5 or 10 kHz off frequency to put the signal into the skirts of the IF passband. If your hand-held is dual-band (144/440 MHz) and you are hunting on 144 MHz, try tuning to the much weaker third harmonic of the signal in the 440-MHz band.

The body fade null, which is rather shallow to begin with, can be obscured by reflections, multipath, nearby objects, etc. Step well away from your vehicle before trying to get a bearing. Avoid large buildings, chain-link fences, metal signs and the like. If you do not get a good null, move to a clearer location and try again.

## Air Attenuators

In microwave parlance, a signal that is too low in frequency to be propagated in a waveguide (that is, below the *cutoff frequency*) is attenuated at a predictable logarithmic rate. In other words, the farther inside the waveguide, the weaker the signal gets. Devices that use this principle to reduce signal strength are commonly

strong RF field, some energy will be coupled directly into the receiver circuitry. When this happens, the S-meter reading changes only slightly or perhaps not at all as the RDF antenna rotates, no matter how much attenuation you add. The cure is to shield the receiving equipment. Something as simple as wrapping the receiver in foil or placing it in a bread pan or cake pan, covered with a piece of copper or aluminum screening securely fastened at several points, may reduce direct pickup enough for you to get bearings.

Alternatively, you can replace the receiver with a field-strength meter as you close in, or use a heterodyne-type active attenuator. Plans for these devices are at the end of this chapter.

## The Body Fade

A crude way to find the direction of a VHF signal with just a hand-held receiver is the body fade technique, so named

because the blockage of your body causes the signal to fade. Hold your HT close to your chest and turn all the way around slowly. Your body is providing a shield that

**Fig 23.89** — When performing the body fade maneuver, a hand-held transceiver exhibits this directional pattern.

**Fig 23.90** — The air attenuator for a VHF hand-held in use. Suspend the radio by the wrist strap or a string inside the tube.

known as *air attenuators*. Plans for a practical model for insertion in a coax line are in *Transmitter Hunting* (see Bibliography).

With this principle, you can reduce the level of strong signals into your hand-held transceiver, making it possible to use the body fade technique at very close range. Glen Rickerd, KC6TNF, documented this technique for *QST*. Start with a pasteboard mailing tube that has sufficient inside diameter to accommodate your hand-held. Cover the outside of the tube completely with aluminum foil. You can seal the

bottom end with foil, too, but it probably will not matter if the tube is long enough. For durability and to prevent accidental shorts, wrap the foil in packing tape. You will also need a short, stout cord attached to the hand-held. The wrist strap may work for this, if long enough.

To use this air attenuation scheme for body fade bearings, hold the tube vertically against your chest and lower the hand-held into it until the signal begins to weaken (Fig 23.90). Holding the receiver in place, turn around slowly and listen for

a sudden decrease in signal strength. If the null is poor, vary the depth of the receiver in the tube and try again. You do not need to watch the S-meter, which will likely be out of sight in the tube. Instead, use noise level to estimate signal strength.

For extremely strong signals, remove the "rubber duck" antenna or extend the wrist strap with a shoelace to get greater depth of suspension in the tube. The depth that works for one person may not work for another. Experiment with known signals to determine what works best for you.

## A SIMPLE LOOPSTICK WITH SENSE FOR 3.5 MHz

Figs 23.91, 92 and 93 show an RDF loop suitable for the 3.5 MHz band. With appropriate changes in core and winding, the basic design is adaptable to other frequencies. The turns are wound on an 8-inch long ferrite rod salvaged from a broadcast antenna loopstick. Because of the high Q achieved with the ferrite core, the sensitivity of this loop is comparable to an air-core loop that is a foot or so in diameter. When the output of the vertical rod sense antenna is properly combined with the output of the loop, the system has a cardioid pattern.

The original version of this unit was re-wound on the rod from a Miller 705-A loopstick, which is no longer available. You may substitute the core from a salvaged AM broadcast set rod antenna (the larger, the better), or obtain a rod of #61 ferrite material from a supplier such as Fair-Rite or Amidon. Start with a 20-turn winding of #22 AWG enamel wire, with a two-turn link wound atop it at the center. Adjust turns as necessary for resonance with C1 and the operating frequency. Secure the windings with electrical tape. A dip meter is helpful for determining the tuning range.

The sensing system is a 15-inch whip and adjustable inductance to resonate the whip at the operating frequency. Potentiometer R1 controls the output of the antenna to match the loop output level. The components, except for rod and whip, mount in a 4x5x3-inch box chassis. To protect the loopstick, secure it inside a piece of 1/2-inch PVC pipe.

### Adjustment

To produce an output having only one null, there must be 90° phase difference between the output of the loop and that of the sense antenna, and signal levels from each must be the same. Obtain the phase shift by tuning the sense antenna slightly

Fig 23.91 — Unidirectional 75-m RDF ferrite-core loop and sense antenna combination. Adjustable components of the circuit are in the aluminum chassis, which is supported by a short length of tubing.

off frequency with the slug in L1, and reduce its output by adjusting R1.

For tune-up, find a clear spot where the transmitter and RDF receiver can be separated by several hundred feet. Use as little power as possible at the test transmitter. Remove any other 75-m antennas from the vicinity of this RDF antenna when testing and transmitter hunting. Turn the loopstick so that one side (not an end) of

Fig 23.93 — Mount the components of the 75-m RDF antenna in the top and sides of an aluminum box. R1 is on the left wall, with C1 below it. S1 and the output connector are on the right wall. Mount the loopstick and whip on the outside.

Fig 23.92 — Circuit of the 75-m rod-sense antenna.

L1 — 40-240-μH adjustable (Miller 9011

or equivalent).  
R1 — 1-kΩ carbon potentiometer.  
S1 — SPST toggle.  
Loopstick — See text.

the rod points toward the test transmitter. With the test transmitter operating on the proper frequency and sense antenna disconnected with S1, peak the loopstick with C1, using the receiver's S-meter.

Next, rotate the rod so that one end points to the test transmitter. Connect the sense antenna and turn R1 to minimum resistance. Vary the adjustable slug of L1 for maximum reading of the S-meter. The

last turn of the slug is quite critical. You may notice some effects of hand capacitance.

Now turn the rod broadside to the signal again. Turn R1 a complete revolution. If you chose the proper side, you should observe a definite null on the S-meter for one position of R1. If not, turn the antenna 180° and try again. Leave R1 at the setting that produces the minimum reading. Now adjust L1 very slowly until the S-meter

reading goes down still further. Repeat this alternating adjustment of R1 and L1 several times until you achieve the best minimum.

Finally, as a check, move the test transmitter around the RDF vehicle and follow it by turning the antenna. If everything is proper, the cardioid null will always be broadside to the loopstick. Make a note of the proper side of the unit for this null.

## A SHIELDED LOOP-SENSE ANTENNA FOR 28 MHz

Fig 23.94 shows the construction and mounting of a simple shielded 28-MHz loop, made from an 18-inch length of RG-11 (solid or foamed dielectric). Mount the coax loop to a small aluminum box with two coaxial cable hoods. Make a break in the outer shield at the exact center, as shown. C1 is a 25-pF variable capacitor, connected in parallel with a C3, a 33-pF mica padder capacitor. C2 is a small differential capacitor to provide electrical symmetry. The download to the receiver is RG-59 cable, 67 inches long if solid dielectric and 82 inches if foamed dielectric.

Compared to VHF Yagis and quads, this loop is easy to mount on a mobile because of its light weight and low wind resistance. The loop gives accurate bearings when held well outside the window if the signal is coming toward that side of the car. However, it is better to mount the loop atop a tall mast through the sunroof or well above the window opening. The car broadcast antenna or a 28-MHz whip on the vehicle may interfere with accurate bearings. Disconnect the antenna or lower it and verify that this resolves the problem.

To find out which of the bidirectional nulls indicates the correct signal direction, add a sense antenna. Mount a phono jack to the top of the aluminum case. Connect the insulated center terminal of the jack to the side of the tuning capacitors connected to the center conductor of the coax download. Attach a short vertical antenna made of brazing rod or stiff wire to the jack. Start with a vertical antenna length of four times the loop diameter and prune it until the loop/sense pattern is similar to a cardioid pattern. It may not be possible to achieve a perfect single-null pattern, but you should be able to use the sense whip to determine which of the figure-8 nulls to follow.

Fig 23.94 — Construction details of the 28-MHz RDF loop. The outer braid of the coax loop is broken at the center of the loop. Cover the gap with waterproof tape and give the assembly a coat of acrylic spray.

The Simple Seeker for 144 MHz is the latest in a series of dual-antenna TDOA projects by Dave Geiser, WA2ANU. Fig 23.79 and accompanying text shows its principle of operation. It is simple to perform rapid antenna switching with diodes, driven by a free-running multivibrator. For best RDF performance, the switching pulses should be square waves, so antennas are alternately connected for equal times. The Simple Seeker uses a CMOS version of the popular 555 timer, which demands very little supply current. A 9-V alkaline battery will give long life. See **Fig 23.95** for the schematic diagram.

Motorola MPN3401 and similar types are suitable. Ordinary 1N4148 switching diodes are acceptable for receive-only use.

tuning, an off-frequency target signal, or misalignment in the receiver IF stages.

Almost any audio transformer with approximately 10:1 voltage step-up to a center-tapped secondary meets the requirements of this phase detector. The output is a positive or negative indication, applied to meter M1 to indicate left or right.

Dipole antennas are best for long-distance RDF. They ensure maximum signal pickup and provide the best load for transmitting. **Fig 23.96** shows plans for a pair of dipoles mounted on an H frame of 1/2-inch PVC tubing. Connect the 39-inch elements to the switcher with coaxial cables of *exactly* equal length. Spacing

between dipoles is about 20 inches for 2 m, but is not critical. To prevent external currents flowing on the coax shield from disrupting RDF operation, wrap three turns (about 2 inch diameter) of the incoming coax to form a choke balun.

For receive-only work, dipoles are effective over much more than their useful transmit bandwidth. A pair of appropriately spaced 144-MHz dipoles works from 130 to 165 MHz. You will get greater tone amplitude with greater dipole spacing, making it easier to detect the null in the presence of modulation on the signal. But do not make the spacing greater than one-half free-space wavelength on any frequency to be used.

Best bearing accuracy demands that signals reach the receiver only from the switched antenna system. They should not arrive on the receiver wiring directly (through an unshielded case) or enter on wiring other than the antenna coax. The phase detecting system is less amplitude sensitive than systems such as quads and Yagis, but if you use small-aperture antennas such as "rubber duckies," a small signal leak may have a big effect. A wrap of aluminum foil around the receiver case helps block unwanted signal pickup, but tighter shielding may be needed.

Fig 23.97 shows a "sniffer" version of the unit with helix antennas. The added RDF circuits fit in a shielded box, with the switching pulses fed through a low-pass filter (the series 4.7-k $\Omega$  resistor and shunt 470-pF capacitor) to the receiver. The electronic switch is on a 20-pin DIP pad, with the phase detector on another pad (see Fig 23.98).

Because the phase detector may behave differently on weak and strong signals, the Simple Seeker incorporates an audio attenuator to allow either a full-strength audio or a lesser, adjustable received signal to feed the phase detector. You can plug headphones into jack AF2 and connect receiver audio to jack AF1 for no attenuation into the phase detector, or reverse the external connections, using the pad to control level to both the phones and the phase detector.

Convention is that the meter or other indicator deflects left when the signal is to the left. Others prefer that a left meter indication indicates that the antenna is rotated too far to the left. Whichever your choice, you can select it with the DPDT polarity switch. Polarity of audio output varies between receivers, so test the unit and receiver on a known signal source and mark the proper switch position on the unit

**Fig 23.96 — "H" frame for the dual dipole Simple Seeker antenna set, made from 1/2-in. PVC tubing and tees. Glue the vertical dipole supports to the tees. Connect vertical tees and handle to the cross piece by drilling both parts and inserting large cotter pins. Tape the dipole elements to the tubes.**

before going into the field.

PIN diodes, when forward biased, exhibit low RF resistance and can pass up to approximately 1 W of VHF power without

damage. The transmit position on the function switch applies steady dc bias to one of the PIN diodes, allowing communications from a hand-held RDF transceiver.

## AN ACTIVE ATTENUATOR FOR VHF-FM

During a VHF transmitter hunt, the strength of the received signal can vary from roughly a microvolt at the starting point to nearly a volt when you are within inch of the transmitter, a 120-dB range. If you use a beam or other directional array, your receiver must provide accurate signal-strength readings throughout the hunt.

Zero to full scale range of S-meters on most hand-held transceivers is only 20 to 30 dB, which is fine for normal operating, but totally inadequate for transmitter hunting. Inserting a passive attenuator between the antenna and the receiver reduces the receiver input signal. However, the usefulness of an external attenuator is limited

by how well the receiver can be shielded.

Anjo Eenhoorn, PA0ZXR, has designed a simple add-on unit that achieves continuously variable attenuation by mixing the received signal with a signal from a 500-kHz oscillator. This process creates mixing products above and below the input frequency. The spacing of the closest products from the input frequency is equal to the local oscillator (LO) frequency. For example, if the input signal is at 146.52 MHz, the closest mixing products will appear at 147.02 and 146.02 MHz.

The strength of the mixing products varies with increasing or decreasing LO signal level. By DFing on the mixing product frequencies, you can obtain accurate headings even in the presence of a very strong received signal. As a result, any hand-held transceiver, regardless of how poor its shielding may be, is usable for transmitter hunting, up to the point where complete blocking of the receiver front end occurs. At the mixing product frequencies, the attenuator's range is greater than 100 dB.

Varying the level of the oscillator signal provides the extra advantage of controlling the strength of the input signal as it passes through the mixer. So as you close in on the target, you have the choice of monitoring and controlling the level of the input signal or the product signals, whichever provides the best results.

The LO circuit (Fig 23.99) uses the easy-to-find 2N2222A transistor. Trimmer capacitor C1 adjusts the oscillator's frequency. Frequency stability is only a minor concern; a few kilohertz of drift is tolerable. Q1's output feeds an emitter-follower buffer using a 2N3904 transistor, Q2. A linear-taper potentiometer (R6) controls the oscillator signal level present at the cathode of the mixing diode, D1. The diode and coupling capacitor C7 are in series with the signal path from antenna input to attenuator output.

This frequency converter design is unorthodox; it does not use the conventional configuration of a doubly balanced mixer, matching pads, filters and so on. Such sophistication is unnecessary here. This approach gives an easy to build circuit that consumes very little power. PA0ZXR uses a tiny 1.4-V hearing-aid battery with a homemade battery clip. If your enclosure permits, you can substitute a standard AAA-size battery and holder.

### Construction and Tuning

ARRL Headquarters will supply the PC board etching template and parts overlay for this project. Request the Eenhoorn Active Attenuator template package from the ARRL Technical Secretary. A circuit

C1 — 75-pF miniature foil trimmer.

J1, J2 — BNC female connectors.

L1 — 470- $\mu\text{H}$  RF choke.

L2 — 3.3- $\mu\text{H}$  RF choke.

R6 — 1-k $\Omega$ , 1-W linear taper (slide or rotary).

S1 — SPST toggle.

Fig 23.100 — Interior view of the active attenuator. Note that C7, D1 and L2 are mounted between the BNC connectors. R5 (not visible in this photograph) is connected to the wiper of slide pot R6.

board is available from FAR Circuits. The prototype (**Fig 23.100**) uses a plated enclosure with female BNC connectors for RF input and output. C7, D1, L2 and R5 are installed with point-to-point wiring between the BNC connectors and the potentiometer. S1 mounts on the rear wall of the enclosure.

Most hams will find the 500-kHz frequency offset convenient, but the oscillator can be tuned to other frequencies. If VHF/UHF activity is high in your area, choose an oscillator frequency that creates mixing products in clear portions of the band. The attenuator was designed for 144-MHz RDF, but will work elsewhere in the VHF/UHF range.

You can tune the oscillator with a frequency counter or with a strong signal of known frequency. It helps to enlist the aid of a friend with a hand-held transceiver a short distance away for initial tests. Connect a short piece of wire to J1, and cable your hand-held transceiver to J2. Select a simplex receive frequency and have your assistant key the test transmitter at its lowest power setting. (Better yet, attach the transmitter to a dummy antenna.)

With attenuator power on, adjust R6 for mid-scale S-meter reading. Now retune the hand-held to receive one of the mixing products. Carefully tune C1 and R6 until you hear the mixing product. Watch the S-meter and tune C1 for maximum reading.

If your receiver features memory channels, enter the hidden transmitter frequency along with both mixing product frequencies before the hunt starts. This allows you to jump from one to the other at the press of a button.

When the hunt begins, listen to the fox's frequency with the attenuator switched on. Adjust R6 until you get a peak reading. If the signal is too weak, connect your quad or other RDF antenna directly to your transceiver and hunt without the attenuator until the signal becomes stronger.

As you get closer to the fox, the attenuator will not be able to reduce the on-frequency signal enough to get good bearings. At this point, switch to one of the mixing product frequencies, set R6 for on-scale reading and continue. As you make your final approach, stop frequently to adjust R6 and take new bearings. At very close range, remove the RDF antenna altogether and replace it with a short piece of wire. It's a good idea to make up a short length of wire attached to a BNC fitting in advance, so you do not damage J1 by sticking random pieces of wire into the center contact.

While it is most convenient to use this system with receivers having S-meters, the meter is not indispensable. The active attenuator will reduce signal level to a point where receiver noise becomes audible. You can then obtain accurate fixes with null-seeking antennas or the "body fade" technique by simply listening for maximum noise at the null.

one of us has the time or space to collect all the literature available on the many different commercially available manufactured components. Even if we did, the task of keeping track of new and obsolete devices would surely be formidable. Fortunately, amateurs tend to use a limited number of component types. This chapter, by Douglas Heacock, AAØMS, provides information on the components most often used by the Amateur Radio experimenter.

### COMPONENT VALUES

Throughout this *Handbook*, composition resistors and small-value capacitors are specified in terms of a system of "preferred values." This system allows manufacturers to supply these components in a standard set of values, which, when considered

along with component tolerances, satisfy the vast majority of circuit requirements.

The preferred values are based on a roughly logarithmic scale of numbers between 1 and 10. One decade of these values for three common tolerance ratings is shown in **Table 24.1**.

The Table represents the two significant digits in a resistor or capacitor value. Multiply these numbers by multiples of ten to get other standard values. For example, 22 pF, 2.2  $\mu$ F, 220  $\mu$ F, and 2200  $\mu$ F are all standard capacitance values, available in all three tolerances. Standard resistor values include 3.9  $\Omega$ , 390  $\Omega$ , 39,000  $\Omega$  and 3.9 M $\Omega$  in  $\pm 5\%$  and  $\pm 10\%$  tolerances. All standard resistance values, from less than 1  $\Omega$  to about 5 M $\Omega$  are based on this table.

Each value is greater than the next smaller value by a multiplier factor that depends on the tolerance. For  $\pm 5\%$  devices, each value is approximately 1.1 times the next lower one. For  $\pm 10\%$  devices, the multiplier is 1.21, and for  $\pm 20\%$  devices, the multiplier is 1.47. The resultant values are rounded to make up the series.

Tolerance refers to a range of accept-

able values above and below the specified component value. For example, a 4700- $\Omega$  resistor rated for  $\pm 20\%$  tolerance can have an actual value anywhere between 3760  $\Omega$  and 5640  $\Omega$ . You may always substitute a closer-tolerance device for one with a wider tolerance. For projects in this *Handbook*, assume a 10% tolerance if none is specified.

### COMPONENT MARKINGS

The values, tolerances or types of most small components are typically marked with a color code or an alphanumeric code according to standards agreed upon by component manufacturers. The Electronic Industries Association (EIA) is a US agency that sets standards for electronic components, testing procedures, performance and device markings. The EIA cooperates with other standards agencies such as the International Electrotechnical Commission (IEC), a world-wide standards agency. You can often find published EIA standards in the engineering library of a college or university.

The standard EIA color code is used to identify a variety of electronic compo-

nents. Most resistors are marked with color bands according to the code, shown in Table 24.2. Some types of capacitors and inductors are also marked using this color code.

## Resistor Markings

Carbon-composition, carbon-film, and metal-film resistors are typically manufactured in roughly cylindrical cases with axial leads. They are marked with color bands as shown in Fig 24.1A. The first two bands represent the two significant digits of the component value, the third band represents the multiplier, and the fourth band (if there is one) represents the tolerance. Some units are marked with a fifth band that represents the percentage of resistance change per 1000 hours of operation: brown = 1%; red = 0.1%; orange = 0.01%; and yellow = 0.001%. Precision resistors (EIA Std RS-279, Fig 24.1B) and some mil-spec (MIL STD-1285A) resistors also use five color bands. On precision resistors, the first three bands are used for significant figures and the space between the fourth and fifth bands is wider than the others, to identify the tolerance band. On the military resistors, the fifth band indicates reliability information such as failure rate.

For example, if a resistor of the type shown in Fig 24.1A is marked with A = red; B = red; C = orange; D = no color, the significant figures are 2 and 2, the multiplier is 1000, and the tolerance is ±20%.

Table 24.5

## EIA Capacitor Tolerance Codes

Code	Tolerance
C	±1/4 pF
D	±1/2 pF
F	±1 pF or ±1%
G	±2 pF or ±2%
J	±5%
K	±10%
L	±15%
M	±20%
N	±30%
P or GMV*	-0%, +100%
W	-20%, +40%
Y	-20%, +50%
Z	-20%, +80%

\*GMV = guaranteed minimum value.

The device is a 22,000-Ω, ±20% unit.

Some resistors are made with radial leads (Fig 24.1C) and are marked with a color code in a slightly different scheme. For example, a resistor as shown in Fig 24.1C is marked as follows: A (body) = blue; B (end) = gray; C (dot) = red; D (end) = gold. The significant figures are 6 and 8, the multiplier is 100, and the tolerance is ±5%; 6800 Ω with ±5% tolerance.

## Resistor Power Ratings

Carbon-composition and metal-film resistors are available in standard power ratings of 1/10, 1/8, 1/4, 1/2, 1 and 2 W. The 1/10- and 1/8-W sizes are relatively expensive and difficult to purchase in small quantities. They are used only where miniaturization is essential. The 1/4, 1/2, 1, and 2-W composition resistor packages are drawn to scale in Fig 24.2. Metal-film resistors are typically slightly smaller than carbon-composition units of the same power rating. Film resistors can usually be identified by a glossy enamel coating and an hour-glass profile. Carbon-film and metal-film are the most commonly available resistors today, having largely replaced the less-stable carbon-composition resistors.

Fig 24.4—Color coding for tubular encapsulated RF chokes. At A, an example of the coding for an 8.2-μH choke is given. At B, the color bands for a 330-μH inductor are illustrated. The color code is given in Table 24.2.

## Capacitor Markings

A variety of systems for capacitor markings are in use. Some use color bands, some use combinations of numbers and letters. Capacitors may be marked with their value, tolerance, temperature characteristics, voltage ratings or some subset of these specifications. Fig 24.3 shows several popular capacitor marking systems.

In addition to the value, ceramic disk capacitors may be marked with an alphanumeric code signifying temperature characteristics. Table 24.3 explains the EIA code for ceramic-disk capacitor temperature characteristics. The code is made up of one character from each column in the table. For example, a capacitor marked Z5U is suitable for use between +10 and +85°C, with a maximum change in capacitance of -56% or +22%.

Capacitors with highly predictable temperature coefficients of capacitance are sometimes used in oscillators that must be frequency stable with temperature. If an application called for a temperature coefficient of -750 ppm/°C (N750), a capacitor marked U2J would be suitable. The older industry code for these ratings is being replaced with the EIA code shown in Table 24.4. NP0 (that is, N-P-zero) means "negative, positive, zero;" it is a characteristic often specified for RF circuits requiring temperature stability, such

**Table 24.6****SMT Resistor Tolerance Codes**

Letter	Tolerance
D	±0.5%
F	±1.0%
G	±2.0%
J	±5.0%

**Table 24.7****SMT Capacitor Significant Figures Code**

Character	Significant Figures	Character	Significant Figures
A	1.0	T	5.1

Q	3.9	t	8.0
R	4.3	y	9.0
S	4.7		

**Table 24.8****SMT Capacitor Multiplier Codes**

Numeric Character	Decimal Multiplier
0	1
1	10
2	100
3	1,000
4	10,000
5	100,000
6	1,000,000
7	10,000,000
8	100,000,000
9	0.1

as VFOs. A capacitor of the proper value marked C0G is a suitable replacement for an NP0 unit.

Some capacitors, such as dipped silver-mica units, have a letter designating the capacitance tolerance. These letters are deciphered in **Table 24.5**.

### Surface-Mount Resistor and Capacitor Markings

Many different types of electronic components, both active and passive, are now available in surface-mount packages. These are commonly-known as chip resistors

and capacitors. The very small size of these components leaves little space for marking with conventional codes, so brief alphanumeric codes are used to convey the most information in the smallest possible space.

Surface-mount resistors are typically marked with a three- or four-digit value code and a character indicating tolerance. The nominal resistance, expressed in ohms, is identified by three digits for 2% (and greater) tolerance devices. The first two digits represent the significant figures; the last digit specifies the multiplier as the exponent of ten. (It may be easier to remember the multiplier as the number of zeros you must add to the significant figures.) For values less than 100  $\Omega$ , the letter R is substituted for one of the significant digits and represents a decimal point. Here are some examples:

Resistor Code	Value
101	10 and 1 zero = 100 $\Omega$
224	22 and 4 zeros = 220,000 $\Omega$
1R0	1.0 and no zeros = 1 $\Omega$
22R	22.0 and no zeros = 22 $\Omega$
R10	0.1 and no zeros = 0.1 $\Omega$

If the tolerance of the unit is narrower than  $\pm 2\%$ , the code used is a four-digit code where the first three digits are the significant figures and the last is the multiplier. The letter R is used in the same way to represent a decimal point. For example, 1001 indicates a 1000- $\Omega$  unit, and 22R0 indicates a 22- $\Omega$  unit.

The tolerance rating for a surface-mount resistor is expressed with a single character at the end of the numeric value code, according to **Table 24.6**.

Surface-mount capacitors are marked with a two-character code consisting of a letter indicating the significant digits (see **Table 24.7**) and a number indicating the multiplier (see **Table 24.8**). The code represents the capacitance in picofarads. For example, a chip capacitor marked "A4" would have a capacitance of 10,000 pF, or 0.01  $\mu\text{F}$ . A unit marked "N1" would be a 33-pF capacitor. If there is sufficient space on the device package, a tolerance code may be included (see Fig 24.3D for tolerance codes). Surface-mount capacitors can be very small; you may need a magnifying glass to read the markings.

### INDUCTORS AND CORE MATERIALS

Inductors, both fixed and variable, are available in a wide variety of types and packages, and many offer few clues as to their values. Some coils and chokes are marked with the EIA color code shown in **Table 24.2**. See **Fig 24.4** for another mark-

**Fig 24.5—Color coding for semiconductor diodes.** At A, the cathode is identified by the double-width first band. At B, the bands are grouped toward the cathode. Two-figure designations are signified by a black first band. The color code is given in **Table 24.2**. The suffix-letter code is A—Brown, B—red, C—orange, D—yellow, E—green, F—blue. The 1N prefix is understood.

ing system for tubular encapsulated RF chokes.

Most powdered-iron toroid cores that we amateurs use are manufactured by Micrometals, who uses paint to identify the material used in the core. The Micrometals color code is part of **Table 24.9**. **Table 24.10** gives the physical characteristics of powdered-iron toroids. Ferrite cores are not typically painted, so identification is more difficult. See **Table 24.11** for information about ferrite cores.

### TRANSFORMERS

Many transformers, including power transformers, IF transformers and audio transformers, are made to be installed on PC boards, and have terminals designed for that purpose. Some transformers are manufactured with wire leads that are color-coded to identify each connection. When colored wire leads are present, the color codes in **Tables 24.12**, **24.13** and **24.14** usually apply.

In addition, many miniature IF transformers are tuned with slugs that are color-coded to signify their application. **Table 24.15** lists application vs slug color.

### SEMICONDUCTORS

Most semiconductor devices are clearly marked with the part number and in some cases, a manufacturer's date code as well.

**Table 24.9**  
**Powdered-Iron Toroid Cores: Magnetic Properties**

*Inductance and Turns Formula*

The turns required for a given inductance or inductance for a given number of turns can be calculated from:

$$N=100\sqrt{\frac{L}{A_L}} \quad L=A_L\left(\frac{N^2}{10,000}\right)$$

where N = number of turns; L = desired inductance (μH);  $A_L$  = inductance index (μH per 100 turns).

$A_L$  Values (μH per 100 turns)

Size	Mix										
	26*	3	15	1	2	7	6	10	12	17	0

\*Mix-26 is similar to the older Mix-41, but can provide an extended frequency range.

*Magnetic Properties Iron Powder Cores*

Mix	Color	Material	μ	Temp stability (ppm/°C)	f (MHz)	Notes
26	Yellow/white	Hydrogen reduced	75	825	dc - 1	Used for EMI filters and dc chokes
3	Gray	Carbonyl HP	35	370	0.05 - 0.50	Excellent stability, good Q for lower frequencies
15	Red/white	Carbonyl GS6	25	190	0.10 - 2	Excellent stability, good Q
1	Blue	Carbonyl C	20	280	0.50 - 5	Similar to Mix-3, but better stability
2	Red	Carbonyl E	10	95	2 - 30	High Q material
7	White	Carbonyl TH	9	30	3 - 35	Similar to Mix-2 and Mix-6, but better temperature stability
6	Yellow	Carbonyl SF	8	35	10 - 50	Very good Q and temp. stability for 20-50 MHz
10	Black	Powdered iron W	6	150	30 - 100	Good Q and stability for 40 - 100 MHz
12	Green/white	Synthetic oxide	4	170	50 - 200	Good Q, moderate temperature stability
17	Blue/yellow	Carbonyl	4	50	40 - 180	Similar to Mix-12, better temperature stability, Q drops about 10% above 50 MHz, 20% above 100 MHz
0	Tan	phenolic	1	0	100 - 300	Inductance may vary greatly with winding technique

Courtesy of Amidon Assoc and Micrometals

Note: Color codes hold only for cores manufactured by Micrometals, which makes the cores sold by most Amateur Radio distributors.

Identification of semiconductors can be difficult, however, when the parts are "house-marked" (marked with codes used by an equipment manufacturer instead of the standard part numbers). In such cases, it is often possible to find the standard equivalent or a suitable replacement by using one of the semiconductor cross-reference directories available from various replacement-parts distributors. If you look up the house number and find the recommended replacement part, you can often find other standard parts that are replaced by that same part.

### Diodes

Most diodes are marked with a part number and some means of identifying which lead is the cathode. Some diodes are marked with a color-band code (see Fig 24.5). Important diode parameters include maximum forward current, maximum peak inverse voltage (PIV) and the power-handling capacity.

### Transistors

Some important parameters for transistor selection are voltage and current limits, power-handling capability, beta or

gain characteristics and useful frequency range. The case style may also be an issue; some transistors are available in several different case styles.

### Integrated Circuits

Integrated circuits (ICs) come in a variety of packages, including transistor-like metal cans, dual and single in-line packages (DIPs and SIPs), flat-packs and surface-mount packages. Most are marked with a part number and a four-digit manufacturer's date code indicating the year (first two digits) and week (last two digits) that the component

Actual number of turns may differ from above figures according to winding techniques, especially when using the larger size wires. Chart prepared by Michel J. Gordon, Jr., WB9FHC  
Courtesy of Amidon Assoc.

was made. ICs are frequently house-marked, and the cross-reference directories mentioned above can be helpful in identification and replacement.

Another very useful reference tool for working with ICs is *IC Master*, a master selection guide that organizes ICs by type, function and certain key parameters. A part number index is included, along with application notes and manufacturer's information for tens of thousands of IC devices. Some of the data from *IC Master* is also available on computer disks.

IC part numbers usually contain a few digits that identify the circuit die or function and several other letters and/or digits that identify the production process, manufacturer and package. For example, a '4066 IC contains four independent SPST switches. Harris (CD74HC4066, CD4066B and CD4066BE), National (MM74HC4066, CD4066BC and CD4066BM) and Panasonic (MN74HC4066

and MN4066B) all make similar devices (as do many other manufacturers) with slight differences. Among the numbers listed, "CD" (CMOS Digital), "MM" (MOS Monolithic), and "MN" indicate CMOS parts. "74" indicates a commercial quality product (for applications from 0°C to 70°C), which is pin compatible with the 74/54 TTL families. "HC" means high-speed CMOS family, which is as fast as the LS TTL family. The "B" suffix, as is CD4066B, indicates a buffered output. This is only a small example of the conventions used in IC part numbers. For more information look at data books from the various manufacturers. Base diagrams for many common ICs appear in *The ARRL Electronics Data Book*.

When choosing ICs that are not exact replacements, several operating needs and performance aspects should be considered. First, the replacement power requirements must be met: Some ICs require 5 V dc, others 12 V and some need both posi-

tive and negative supplies. Current requirements vary among the various IC families, so be sure that sufficient current is available from the power supply. If a replacement IC uses much more current than the device it replaces, a heat sink or blower may be needed to keep it cool.

Next consider how the replacement interacts with its neighboring components. Input capacitance and "fanout" are critical factors in digital circuits. Increased input capacitance may overload the driving circuits. Overload slows circuit operation, which may prevent lines from reaching the "high" condition. Fanout tells how many inputs a device can drive. The fanout of a replacement should be equal to, or greater than, that required in the circuit. Operating speed and propagation delay are also significant. Choose a replacement IC that operates at or above the circuit clock speed. (Although increased speed can increase EMI and cause other problems.) Some circuits may not function if the propagation delay varies much from the specified part. Look at the **Digital** chapter for details of how these operating characteristics relate to circuit performance.

Analog ICs have similar characteristics. Input and output capacities are often defined as how much current an analog IC can "sink" (accept at an input) or "source" (pass to a load). A replacement should be able to source or sink at least as much current as the device it replaces. Analog speed is sometimes listed as bandwidth (as in discrete-component circuits) or slew rate (common in op amps). Each of these quantities should meet or exceed that of the replaced component.

Some ICs are available in different operating temperature ranges. Op amps, for example, are commonly available in three standard ranges:

- Commercial 0°C to 70°C
- Industrial -25°C to 85°C
- Military -55°C to 125°C

In some cases, part numbers reflect the temperature ratings. For example, an LM301A op amp is rated for the commercial temperature range; an LM201A op amp for the industrial range and an LM101A for the military range.

When necessary, you can add interface circuits or buffer amplifiers that improve the input and output capabilities of replacement ICs, but auxiliary circuits cannot improve basic device ratings, such as speed or bandwidth.

An excellent source of information on many common ICs is *The ARRL Electronics Data Book*, which contains detailed data for digital ICs (CMOS and TTL), op amps and other analog ICs.

**Table 24.12****Power-Transformer Wiring Color Codes**

Non-tapped primary leads:	Black
Tapped primary leads:	Common: Black
	Tap: Black/yellow striped
	Finish: Black/red striped
High-voltage plate winding:	Red
Center tap:	Red/yellow striped
Rectifier filament winding:	Yellow
Center tap:	Yellow/blue striped
Filament winding 1:	Green
Center tap:	Green/yellow striped
Filament winding 2:	Brown
Center tap:	Brown/yellow striped
Filament winding 3:	Slate
Center tap:	Slate/yellow striped

**OTHER SOURCES OF COMPONENT DATA**

There are many sources you can consult for detailed component data. Many manu-

facturers publish data books for the components they make. Many distributors will include data sheets for parts you order if you ask for them. Parts catalogs them-

**Table 24.13****IF Transformer Wiring Color Codes**

Plate lead:	Blue
B+ lead:	Red
Grid (or diode) lead:	Green
Grid (or diode) return:	Black

Note: If the secondary of the IF transformer is center-tapped, the second diode plate lead is green-and-black striped, and black is used for the center-tap lead.

**Table 24.14****IF Transformer Slug Color Codes**

Frequency	Application	Slug color
455 kHz	1st IF	Yellow
	2nd IF	White
	3rd IF	Black
	Osc tuning	Red
10.7 MHz	1st IF	Green
	2nd or 3rd IF	Orange, Brown or Black

**Table 24.15****Audio Transformer Wiring Color Codes**

Plate lead of primary	Blue
B+ lead (plain or center-tapped)	Red
Plate (start) lead on center-tapped primaries	Brown (or blue if polarity is not important)
Grid (finish) lead to secondary	Green
Grid return (plain or center tapped)	Black
Grid (start) lead on center tapped secondaries	Yellow (or green if polarity not important)

Note: These markings also apply to line-to-grid and tube-to-line transformers.

## Teflon Coated, Stranded Wire

(As supplied by Belden Wire and Cable)

Size	Strands <sup>5</sup>	Turns per Linear inch <sup>2</sup> UL Style No.		
		1180	1213	1371
16	19×29	11.2		
18	19×30	12.7		
20	7×28	14.7	17.2	
20	19×32	14.7	17.2	
22	19×34	16.7	20.0	23.8
22	7×30	16.7	20.0	23.8
24	19×36	18.5	22.7	27.8
24	7×32		22.7	27.8
26	7×34		25.6	32.3
28	7×36		28.6	37.0
30	7×38		31.3	41.7
32	7×40			47.6

### Notes

<sup>1</sup>A circular mil (CM) is a unit of area equal to that of a one-mil-diameter circle ( $\pi/4$  square mils). The CM area of a wire is the square of the mil diameter.

<sup>2</sup>Figures given are approximate only; insulation thickness varies with manufacturer.

<sup>3</sup>Maximum wire temperature of 212°F (100°C) with a maximum ambient temperature of 13°F (57°C) as specified by the manufacturer. The *National Electrical Code* or local building codes may differ.

<sup>4</sup>700 CM per ampere is a satisfactory design figure for small transformers, but values from 500 to 1000 CM are commonly used. The *National Electrical Code* or local building codes may differ.

<sup>5</sup>Stranded wire construction is given as "count"×"strand size" (AWG).

## Color Code for Hookup Wire

Wire Color	Type of Circuit
Black	Grounds, grounded elements and returns
Brown	Heaters or filaments, off ground
Red	Power supply B plus
Orange	Screen grids and base 2 of transistors
Yellow	Cathodes and transistor emitters
Green	Control grids, diode plates, and base 1 of transistors
Blue	Plates and transistor collectors
Violet	Power supply, minus leads
Gray	Ac power line leads
White	Bias supply, B or C minus, AGC

Note: Wires with tracers are coded in the same manner as solid-color wires, allowing additional circuit identification over solid-color wiring. The body of the wire is white and the color band spirals around the wire lead. When more than one color band is used, the widest band represents the first color.

## Crystal Holders

NOTE: SOLDER SEAL, COLD WELD, AND RESISTANCE WELD SEALING METHODS ARE COMMONLY AVAILABLE.  
NOTE: ALL DIMENSIONS ARE IN INCHES.

\*Note: HC17/U pin spacing and diameter is equivalent to the older FT-243 (32 pF) holder.

## Aluminum Alloy Characteristics

### Common Alloy Numbers

Type	Characteristic
2024	Good formability, high strength
5052	Excellent surface finish, excellent corrosion resistance, normally not heat treatable for high strength
6061	Good machinability, good weldability, can be brittle at high temps
7075	Good formability, high strength

### General Uses

Type	Uses
2024-T3	Chassis boxes, antennas, anything that will be bent or flexed repeatedly
7075-T3	
6061-T6	Mounting plates, welded assemblies or machined parts

### Common Tempers

Type	Characteristics
T0	Special soft condition
T3	Hard
T6	Very hard, possibly brittle
TXXX	Three digit tempers—usually specialized high-strength heat treatments, similar to T6

## Miniature Lamp Guide

### BULB STYLES

\*\*Bulbs are described by a letter indicating shape and a number that is an approximation of diameter expressed in eighths of an inch. For example S-8 is "S" shape, 8 eighths or 1 inch in diam.

1N5711	Schottky	Si	70	1 m (200 n)	15 m	0.41 @ 1 mA
1N5767	Signal	Si		0.1 (1.0 $\mu$ )		1.0
1N5817	Schottky	Si	20	1.0 (1 m)	25	0.75
1N5819	Schottky	Si	40	1.0 (1 m)	25	0.9
1N5821	Schottky	Si	30	3.0		
ECG5863	RFR	Si	600	6	150	0.9
1N6263	Schottky	Si	70	15 m	50 m	0.41 @ 1 mA
5082-2835	Schottky	Si	8	1 m (100 n)	10 m	0.34 @ 1 mA

Si = Silicon; Ge = Germanium; RFR = rectifier, fast recovery.

† For package shape, size and pin-connection information see manufacturers' data sheets. Many retail suppliers offer data sheets to buyers free of charge on request. Data books are available from many manufacturers and retailers.

## European Semiconductor Numbering System (PRO Electron Code)

**B F R 90**

### First Letter (Material)

- A Germanium
- B Silicon
- C Compound materials such as cadmium sulfide or gallium arsenide used in semiconductor devices (Energy gap band of 1.3 or more electron-volts)
- D Materials with an energy gap band of less than 0.6 electron-volts such as indium antimonide
- R Radiation detectors, photoconductive cells, hall-effect generators and so on

### Second Letter (Type)

- A Low-power diode, voltage-variable capacitor
- B Varicap
- C Small-signal audio transistor
- D Audio power transistor
- E Tunnel diode
- F Small-signal RF transistor
- G Miscellaneous
- H Field probe
- K Hall generator
- L RF-power transistor
- M Hall modulators and multipliers
- P Photodiode, phototransistor, photoconductive cell (LDR), radiation device
- R Low-power controlled rectifier
- S Low-power switching transistor
- T Breakdown devices, high-power controlled rectifier, Schottky diode, Thyristor, pnpn diodes
- U High-power switching transistor
- X Multiplier diode
- Y High-power rectifier (diode)
- Z Zener diode

### Third, Fourth, Fifth Character (Serial Code)

- Y## Industrial service (no letter "Z").  
## is a W## registration number from 10 to 99.
- 100 - Device for consumer or entertainment use.  
999

## Japanese Semiconductor Nomenclature

All transistors manufactured in Japan are registered with the Electronic Industries Association of Japan (EIAJ). In addition, the Japan Industrial Standard JIS-C-7012 provides type numbers for transistors and thyristors.

Each transistor type number contains five elements.

i	ii	iii	iv	v
2	S	C	82D	A
Figure	Letter	Letter	Figure	Letter

i) Kind of device, indicating number of effective electrical connections minus one.

ii) For a semiconductor registered with the EIAJ this letter is always an S.

iii) This letter designates polarity and application, as follows:

Letter	Polarity and Application
A	PNP transistor, high frequency
B	PNP transistor, low frequency
C	NPN transistor, high frequency
D	NPN transistor, low frequency
E	P-gate thyristor
G	N-gate thyristor
H	N-base unijunction transistor
J	P-channel FET
K	N-channel FET
M	Bi-directional triode thyristor

iv) These figures designate the order of application for EIAJ registration, starting with 11.

v) This letter indicates the level of improvement. An improvement device may be used in place of a previous-generation device, but not necessarily the other way around.

## Suggested Small-Signal FETs

## VHF and UHF Class-A Transistors

The devices listed below are recommended for class-A linear applications, and include medium-power parts that are useful at frequencies from 100 MHz to 2 GHz.

Device	Frequency (MHz)	$V_{CC}$ (V)	$P_O$ @ 1 dB Compression (W)	Small Signal Gain/Frequency (MHz)	Bias Point ( $V_{dc}/A$ )	Package

## Three-Terminal Voltage Regulators

Listed numerically by device

Device	Description	Package	Voltage	Current (Amps)
317	Adj Pos	TO-205	+1.2 to +37	0.5
317	Adj Pos	TO-204, TO-220	+1.2 to +37	1.5
317L	Low Current Adj Pos	TO-205, TO-92	+1.2 to +37	0.1
317M	Med Current Adj Pos	TO-220	+1.2 to +37	0.5
338	Adj Pos	TO-3	+1.2 to +32	5.0
350	High Current Adj Pos	TO-204, TO-220	+1.2 to +33	3.0
337	Adj Neg	TO-205	-1.2 to -37	0.5
337	Adj Neg	TO-204, TO-220	-1.2 to -37	1.5
337M	Med Current Adj Neg	TO-220	-1.2 to -37	0.5
309		TO-205	+5	0.2
309		TO-204	+5	1.0
323		TO-204, TO-220	+5	3.0
140-XX	Fixed Pos	TO-204, TO-220	Note 1	1.0
340-XX		TO-204, TO-220		1.0
78XX		TO-204, TO-220		1.0
78LXX		TO-205, TO-92		0.1
78MXX	Fixed Neg	TO-220		0.5
78TXX		TO-204		3.0
79XX		TO-204, TO-220	Note 1	1.0
79LXX		TO-205, TO-92		0.1
79MXX		TO-220		0.5

Note 1—XX indicates the regulated voltage; this value may be anywhere from 1.2 V to 35 V. A 7815 is a positive 15-V regulator, and a 7924 is a negative 24-V regulator.

The regulator package may be denoted by an additional suffix, according to the following:

Package	Suffix
TO-204 (TO-3)	K
TO-220	T
TO-205 (TO-39)	H, G
TO-92	P, Z

For example, a 7812K is a positive 12-V regulator in a TO-204 package. An LM340T-5 is a positive 5-V regulator in a TO-220 package. In addition, different manufacturers use different prefixes. An LM7805 is equivalent to a  $\mu$ A7805 or MC7805.

## KEY TO CLASS-OF-SERVICE ABBREVIATIONS

- A<sub>1</sub> = Class-A<sub>1</sub> AF modulator.  
 AB<sub>1</sub> = Class-AB<sub>1</sub> push-pull AF modulator.  
 AB<sub>2</sub> = Class-AB<sub>2</sub> push-pull AF modulator.  
 B = Class-B push-pull AF modulator.  
 CM = Frequency multiplier.  
 CP = Class-C plate-modulated telephone.

- CT = Class-C CW.  
 CTO = Class-C amplifier-oscillator.  
 AB<sub>2</sub>GG = Grounded-grid class AB<sub>2</sub> amplifier.  
 BGG = Grounded-grid class B amp. (single tone)  
 GGO = Grounded-grid oscillator.  
 GIC = Grid-isolation circuit.  
 GMA = Grid-modulated amplifier.

<sup>2</sup>Values are for two tubes in push-pull.<sup>3</sup>Maximum signal value.<sup>4</sup>Peak AF grid-to-grid volts.<sup>5</sup>Maximum cathode current in mA.<sup>6</sup>Forced-air cooling required.<sup>7</sup>Key-down CW.

## <sup>1</sup> SERVICE CLASS ABBREVIATIONS:

B = Class-B push-pull at modulator.  
 CM = Frequency multiplier.  
 CP = Class-C plate-modulated phone.  
 CT = Class-C telegraph.  
 CTO = Class-C amplifier-oscillator.  
 GG = Grounded-grid (grid and screen connected together).

## <sup>2</sup> Maximum signal value.

## <sup>3</sup> Peak grid-to-grid volts.

## <sup>4</sup> Forced-air cooling required.

## <sup>5</sup> Two tubes triode connected, G<sub>2</sub> to G<sub>1</sub> through 20 kΩ. Input to G<sub>2</sub>.

## <sup>6</sup> Typical operation at 175 MHz.

## <sup>7</sup> ±1.5 V.

## <sup>8</sup> Values are for two tubes.

## <sup>9</sup> Single tone.

## TV Deflection Tubes

Note: For AB<sub>1</sub> operation, input data is average 2-tone value. Output power is PEP.

## EIA Vacuum-Tube Base Diagrams

Base diagrams correspond to the codes in "Base" columns of the tube-data tables. Bottom views are shown throughout. Base connections are abbreviated as follows:

BS—Base sleeve  
F—Filament  
G—Grid  
H—Heater  
IC—Internal connection  
K—Cathode  
NC—No connection  
P—Plate (anode)  
P<sub>BF</sub>—Beam plates  
S—Shell

Alphabetical subscripts (D = diode, P = pentode, T = triode and HX = hexode) indicate structures in multistroke tubes. Subscript CT indicates filament or heater center tap.

Generally, when pin 1 of a metal-envelope tube (except all triodes) is shown connected to the envelope, pin 1 of a glass-envelope counterpart (suffix G or GT) is connected to an internal shield.

## Properties of Common Thermoplastics

### Polyvinyl Chloride (PVC)

#### Advantages:

- can be compounded with plasticizers, fillers, stabilizers, lubricants and impact modifiers to produce a wide range of physical properties
- can be pigmented to almost any color
- Rigid PVC has good corrosion and stain resistance, thermal & electrical insulation, and weatherability

#### Disadvantages:

- base resin can be attacked by aromatic solvents, ketones, aldehydes, naphthalenes, and some chloride, acetate, and acrylate esters
- should not be used above 140°

#### Applications:

- conduit
- conduit boxes
- electrical fittings
- housings
- pipe
- wire and cable insulation

### Polystyrene

#### Advantages:

- low cost
- moderate strength
- electrical properties only slightly affected by temperature and humidity
- sparkling clarity
- impact strength is increased by blending with rubbers, such as polybutadiene

#### Disadvantages:

- brittle
- low heat resistance

#### Applications:

- capacitors
- light shields
- knobs

### Polyphenylene Sulfide (PPS)

#### Advantages:

- excellent dimensional stability
- strong
- high-temperature stability
- chemical resistant
- Inherently completely flame retardant
- completely transparent to microwave radiation.

#### Applications:

- R3-R5 have various glass-fiber levels that are suitable for applications demanding high mechanical and impact strength as well as good dielectric properties.
- R8 and R10 are suitable for high arc-resistance applications
- R9-901 is suitable for encapsulation of electronic devices

### Polypropylene

#### Advantages:

- low density
- good balance of thermal, chemical, and electrical properties
- moderate strength (increases significantly with glass-fiber reinforcement)

#### Disadvantages:

- Electrical properties affected to varying degrees by temperature (as temperature goes up, dielectric strength increases and volume resistivity decreases.)
- Inherently unstable in presence of oxidative and UV radiation

#### Applications:

- Automotive battery cases
- blower housings
- fan blades
- fuse housings
- insulators
- lamp housings
- supports for current-carrying electrical components.
- TV yokes

### Polyethylene (PE)

#### Advantages: Low Density PE

- Good toughness
- excellent chemical resistance
- excellent electrical properties
- low coefficient of friction
- near zero moisture absorption
- easy to process
- relatively low heat resistance

#### Disadvantage

- susceptible to environmental and some chemical stress cracking
- wetting agents (such as detergents) accelerate stress cracking

#### Advantages: High Density PE

- Same as above, plus increased rigidity and tensile strength

#### Advantages: Ultra-High Molecular Weight PE

- outstanding abrasion resistance
- low coefficient of friction
- high impact strength
- excellent chemical resistance
- material does not break in impact strength tests using standard notched specimens

#### Applications:

- bearings
- components requiring maximum abrasion resistance, impact strength, and low coefficient of friction

### Phenolic

#### Advantages:

- low cost
- superior heat resistance
- high heat-deflection temperatures
- good electrical properties
- good flame resistance
- excellent moldability
- excellent dimensional stability
- good water and chemical resistance

#### Applications:

- commutators and housings for small motors
- heavy duty electrical components
- rotary-switch wafers
- insulating spacers

### Nylon

#### Advantages

- excellent fatigue resistance
- low coefficient of friction
- toughness a function of degree of crystallinity
- resists many fuels and chemicals
- good creep- and cold-flow resistance as compared to less rigid thermoplastics
- resists repeated impacts

#### Disadvantages:

- all nylons absorb moisture
- nylons that have not been compounded with a UV stabilizer are sensitive to UV light, and thus not suitable for extended outdoor use

#### Applications

- bearings
- housing and tubing
- rope
- wire coatings
- wire connectors
- wear plates

## Coaxial Cable End Connectors

### UHF Connectors

Military No.	Style	Cable RG- or Description
PL-259	Str (m)	8, 9, 11, 13, 63, 87, 149, 213, 214, 216, 225
UG-111	Str (m)	59, 62, 71, 140, 210
SO-239	Pnl (f)	Std, mica/phenolic insulation
UG-266	Blkhd (f)	Rear mount, pressurized, copolymer of styrene ins.

### Adapters

PL-258	Str (f/f)	Polystyrene ins.
UG-224,363	Blkhd (f/f)	Polystyrene ins.
UG-646	Ang (f/m)	Polystyrene ins.
M-359A	Ang (m/f)	Polystyrene ins.
M-358	T (f/m/f)	Polystyrene ins.

### Reducers

UG-175	55, 58, 141, 142 (except 55A)
UG-176	59, 62, 71, 140, 210

### Family Characteristics:

All are nonweatherproof and have a nonconstant impedance. Frequency range: 0-500 MHz. Maximum voltage rating: 500 V (peak).

### N Connectors

Military No.	Style	Cable RG-	Notes
UG-21	Str (m)	8, 9, 213, 214	50 Ω
UG-94A	Str (m)	11, 13, 149, 216	70 Ω
UG-536	Str (m)	58, 141, 142	50 Ω
UG-603	Str (m)	59, 62, 71, 140, 210	50 Ω

UG-680	Blkhd (f)		Front mount pressurized

### N Adapters

Military No.	Style	Notes
UG-29,A,B	Str (f/f)	50 Ω, TFE ins.
UG-57A,B	Str (m/m)	50 Ω, TFE ins.
UG-27A,B	Ang (f/m)	Mitre body
UG-212A	Ang (f/m)	Mitre body
UG-107A	T (f/m/f)	—
UG-28A	T (f/f/f)	—
UG-107B	T (f/m/f)	—

### Family Characteristics:

N connectors with gaskets are weatherproof. RF leakage: -90 dB min @ 3 GHz. Temperature limits: TFE: -67° to 390°F (-55° to 199°C). Insertion loss 0.15 dB max @ 10 GHz. Copolymer of styrene: -67° to 185°F (-55° to 85°C). Frequency range: 0-11 GHz. Maximum voltage rating: 1500 V P-P. Dielectric withstanding voltage 2500 V RMS. SWR (MIL-C-39012 cable connectors) 1.3 max 0-11 GHz.

### BNC Connectors

Military No.	Style	Cable RG-	Notes
UG-959	Str (m)	8, 9	
UG-260,A	Str (m)	59, 62, 71, 140, 210	Rexolite ins.
UG-262	Pnl (f)	59, 62, 71, 140, 210	Rexolite ins.
UG-262A	Pnl (f)	59, 62, 71, 140, 210	nwx, Rexolite ins.
UG-291	Pnl (f)	55, 58, 141, 142, 223, 400	
UG-291A	Pnl (f)	55, 58, 141, 142, 223, 400	nwx
UG-624	Blkhd (f)	59, 62, 71, 140, 210	Front mount Rexolite ins. Standard
UG-1094A	Blkhd		
UG-625B	Receptacle		
UG-625			

### BNC Adapters

Military No.	Style	Notes
UG-491,A	Str (m/m)	
UG-491B	Str (m/m)	Beryllium, outer contact
UG-914	Str (f/f)	
UG-306	Ang (f/m)	
UG-306A,B	Ang (f/m)	Beryllium outer contact
UG-414,A	Pnl (f/f)	# 3-56 tapped flange holes
UG-306	Ang (f/m)	
UG-306A,B	Ang (f/m)	Beryllium outer contact
UG-274	T (f/m/f)	
UG-274A,B	T (f/m/f)	Beryllium outer contact

### Family Characteristics:

Z = 50 Ω. Frequency range: 0-4 GHz w/low reflection; usable to 11 GHz. Voltage rating: 500 V P-P. Dielectric withstanding voltage 500 V RMS. SWR: 1.3 max 0-4 GHz. RF leakage -55 dB min @ 3 GHz. Insertion loss: 0.2 dB max @ 3 GHz. Temperature limits: TFE: -67° to 390°F (-55° to 199°C); Rexolite insulators: -67° to 185°F (-55° to 85°C). "Nwx" = not weatherproof.

### HN Connectors

Military No.	Style	Cable RG-	Notes
UG-59A	Str (m)	8, 9, 213, 214	
UG-1214	Str (f)	8, 9, 87, 213, 214, 225	Captivated contact
UG-60A	Str (f)	8, 9, 213, 214	Copolymer of styrene ins.
UG-1215	Pnl (f)	8, 9, 87, 213, 214, 225	Captivated contact
UG-560	Pnl (f)		
UG-496	Pnl (f)		
UG-212C	Ang (f/m)		Beryllium outer contact

### Family Characteristics:

Connector Styles: Str = straight; Pnl = panel; Ang = Angle; Blkhd = bulkhead. Z = 50 W. Frequency range = 0-4 GHz. Maximum voltage rating = 1500 V P-P. Dielectric withstanding voltage = 5000 V RMS SWR = 1.3. All HN series are weatherproof. Temperature limits: TFE: -67° to 390°F (-55° to 199°C); copolymer of styrene: -67° to 185°F (-55° to 85°C).

### Cross-Family Adapters

# Circuit Construction

25

Some construction of electronics projects can be a fun part of Amateur Radio. Some folks have said that hams don't build things nowadays; this just isn't so! An ARRL survey shows that 53% of active hams build some electronic projects. When you go to any ham flea market, you see row after row of dealers selling electronic components; people are leaving those tables with bags of parts. They must be doing something with them.

Even experienced constructors will find valuable tips in this chapter. It discusses tools and their uses, electronic construction techniques, tells how to turn a schematic into a working circuit and then summarizes common mechanical construction practices. This chapter was written by Ed Hare, KA1CV, Bruce Hale, KB1MW, Ian White, G3SEK, and Chuck Adams, K5FO.

## SHOP SAFETY

All the fun of building a project will be gone if you get hurt. To make sure this doesn't happen, let's first review some safety rules.

- Read the manual! The manual tells all you need to know about the operation and safety features of the equipment you are using.
- Do not work when you are tired. You will be more likely to make a mistake or forget an important safety rule.
- Never disable any safety feature of any tool. If you do, sooner or later someone will make the mistake the safety feature was designed to prevent.
- Never fool around in the shop. Practical jokes and horseplay are in bad taste at social events; in a shop they are downright dangerous. A work area is a dangerous place at all times; even hand tools

can hurt someone if they are misused.

- Keep your shop neat and organized. A messy shop is a dangerous shop. A knife left laying in a drawer can cut someone looking for another tool; a hammer left on top of a shelf can fall down at the worst possible moment; a sharp tool left on a chair can be a dangerous surprise for the weary constructor who sits down.
- Wear the proper safety equipment. Wear eye-protection goggles when working with chemicals or tools. Use earplugs or earphones when working near noise. If you are working with dangerous chemicals, wear the proper protective clothing.
- Make sure your shop is well ventilated. Paint, solvents, cleaners or other chemicals can create dangerous fumes. If you feel dizzy, get into fresh air immediately, and seek medical help if you do not recover quickly.
- Get medical help when necessary. Every workshop should contain a good first-aid kit. Keep an eye-wash kit near any dangerous chemicals or power tools that can create chips. If you become injured, apply first aid and then seek medical help if you are not sure that you are okay. Even a small burn or scratch on your eye can develop into a serious problem.
- Respect power tools. Power tools are not forgiving. A drill can go through your hand a lot easier than metal. A power saw can remove a finger with ease. Keep away from the business end of power tools. Tuck in your shirt, roll up your sleeves and remove your tie before using any power tool. If you have long hair, tie it back so it can't become entangled in power equipment.
- Don't work alone. Have someone nearby

who can help if you get into trouble when working with dangerous equipment, chemicals or voltages.

- Think! Pay attention to what you are doing. No list of safety rules can cover all possibilities. Safety is always your responsibility. You must think about what you are doing, how it relates to the tools and the specific situation at hand.

## TOOLS AND THEIR USES

All electronic construction makes use of tools, from mechanical tools for chassis fabrication to the soldering tools used for circuit assembly. A good understanding of tools and their uses will enable you to perform most construction tasks.

While sophisticated and expensive tools often work better or more quickly than simple hand tools, with proper use, simple hand tools can turn out a fine piece of equipment. **Table 25.1** lists tools indispensable for construction of electronic equipment. These tools can be used to perform nearly any construction task. Add tools to your collection from time to time, as finances permit.

### Sources of Tools

Radio-supply houses, mail-order stores and most hardware stores carry the tools required to build or service Amateur Radio equipment. Bargains are available at ham flea markets or local neighborhood sales, but beware! Some flea-market bargains are really shoddy imports that won't work very well or last very long. Some used tools are offered for sale because the owner is not happy with their performance.

There is no substitute for quality! A high-quality tool, while a bit more expen-

sive, will last a lifetime. Poor quality tools don't last long and often do a poor job even

when brand new. You don't need to buy machinist-grade tools, but stay away from

cheap tools; they are not the bargains they might appear to be.

**Table 25.1**

## RECOMMENDED TOOLS AND MATERIALS

### Simple Hand Tools

#### Screwdrivers

Slotted, 3-inch, 1/8-inch blade  
Slotted, 8-inch, 1/8-inch blade  
Slotted, 3-inch, 3/16-inch blade  
Slotted, stubby, 1/4-inch blade  
Slotted, 4-inch, 1/4-inch blade  
Slotted, 6-inch, 5/16-inch blade  
Phillips, 2-1/2-inch, #0 (pocket clip)  
Phillips, 3-inch, #1  
Phillips, stubby, #2  
Phillips, 4-inch, #2  
Phillips, 4-inch, #2  
Long-shank screwdriver with holding clip on blade  
Jeweler's set  
Right-angle, slotted and Phillips

#### Pliers, Sockets and Wrenches

Long-nose pliers, 6- and 4-inch  
Diagonal cutters, 6- and 4-inch  
Channel-lock pliers, 6-inch  
Slip-joint pliers  
Locking pliers (Vise Grip or equivalent)  
Socket nut-driver set, 3/16- to 1/2-inch  
Set of socket wrenches for hex nuts  
Allen (hex) wrench set  
Wrench set  
Adjustable wrenches, 6- and 10-inch  
Tweezers, regular and reverse-action  
Retrieval tool/parts holder, flexible claw  
Retrieval tool, magnetic

#### Cutting and Grinding Tools

File set consisting of flat, round, half-round, and triangular. Large and miniature types recommended  
Burnishing tool  
Wire strippers  
Wire crimper  
Hemostat, straight  
Scissors  
Tin shears, 10-inch  
Hacksaw and blades  
Hand nibbling tool (for chassis-hole cutting)  
Scratch awl or scribe (for marking metal)  
Heavy-duty jackknife  
Knife blade set (X-ACTO or equivalent)  
Machine-screw taps, #4-40 through #10-32 thread  
Socket punches, 1/2 in, 5/8 in, 3/4 in, 1-1/8 in, 1-1/4 in, and 1-1/2 in.  
Tapered reamer, T-handle, 1/2-inch maximum width  
Deburring tool

#### Miscellaneous Hand Tools

Combination square, 12-inch, for layout work  
Hammer, ball-peen, 12-oz head  
Hammer, tack  
Bench vise, 4-inch jaws or larger  
Center punch  
Plastic alignment tools  
Mirror, inspection  
Flashlight, penlight and standard

Magnifying glass  
Ruler or tape measure  
Dental pick  
Calipers  
Brush, wire  
Brush, soft  
Small paintbrush  
IC-puller tool

### Hand-Powered Tools

Hand drill, 1/4-inch chuck or larger  
High-speed drill bits, #60 through 3/8-inch diameter

### Power Tools

Motor-driven emery wheel for grinding  
Electric drill, hand-held  
Drill press  
Miniature electric motor tool (Dremel or equivalent) and accessory drill press

### Soldering Tools and Supplies

Soldering pencil, 30-W, 1/8-inch tip  
Soldering iron, 200-W, 5/8-inch tip  
Solder, 60/40, resin core  
Soldering gun, with assorted tips  
Desoldering tool  
Desoldering wick

### Safety

Safety glasses  
Hearing protector, earphones or earplugs  
Fire extinguisher  
First-aid kit

### Useful Materials

Medium-weight machine oil  
Contact cleaner, liquid or spray can  
Duco modeling cement or equivalent  
Electrical tape, vinyl plastic  
Sandpaper, assorted  
Emery cloth  
Steel wool, assorted  
Cleaning pad, Scotchbrite or equivalent  
Cleaners and degreasers  
Contact lubricant  
Sheet aluminum, solid and perforated, 16- or 18-gauge, for brackets and shielding.  
Aluminum angle stock, 1/2x1/2-inch  
1/4-inch-diameter round brass or aluminum rod (for shaft extensions)  
Machine screws: Round-head and flat head, with nuts to fit. Most useful sizes: 4-40, 6-32 and 8-32, in lengths from 1/4-inch to 1-1/2 inches. (Nickel-plated steel is satisfactory except in strong RF fields, where brass should be used.)  
Bakelite, Lucite, polystyrene and copper-clad PC-board scraps.  
Soldering lugs, panel bearings, rubber grommets, terminal-lug wiring strips, varnished-cambric insulating tubing, heat-shrinkable tubing.  
Shielded and unshielded wire.  
Tinned bare wire, #22, #14 and #12.  
Enameled wire, #20 through #30

### Care of Tools

The proper care of tools is more than a matter of pride. Tools that have not been cared for properly will not last long or work well. Dull or broken tools can be safety hazards. Tools that are in good condition do the work for you; tools that are misused or dull are difficult to use.

Store tools in a dry place. Tools do not fit in with most living-room decors, so they are often relegated to the basement or garage. Unfortunately, many basements or garages are not good places to store tools; dampness and dust are not good for tools. If your tools are stored in a damp place, use a dehumidifier. Sometimes you can minimize rust by keeping your tools lightly oiled, but this is a second-best solution. If you oil your tools, they may not rust, but you will end up covered in oil every time you use them. Wax or silicone spray is a better alternative.

Store tools neatly. A messy toolbox, with tools strewn about haphazardly, can be more than an inconvenience. You may waste a lot of time looking for the right tool and sharp edges can be dulled or nicked by tools banging into each other in the bottom of the box. As the old adage says, every tool should have a place, and every tool should be in its place. If you must search the workbench, garage, attic and car to find the right screwdriver, you'll spend more time looking for tools than building projects.

### Sharpening

Many cutting tools can be sharpened. Send a tool that has been seriously dulled to a professional sharpening service. These services can resharpen saw blades, some files, drill bits and most cutting blades. Touch up the edge of cutting tools with a whetstone to extend the time between sharpenings.

Sharpen drill bits frequently to minimize the amount of material that must be removed each time. Frequent sharpening also makes it easier to maintain the critical surface angles required for best cutting with least wear. Most inexpensive drill-bit sharpeners available for shop use do a poor job, either from the poor quality of the sharpening tool or inexperience of the operator. Also, drills should be sharpened at different angles for different applications. Commercial sharpening services do a much better job.

### Intended Purpose

Don't use tools for anything other than

their intended purpose! If you use a pair of wire cutters to cut sheet metal, a pliers as a vise or a screwdriver as a pry bar, you ruin a good tool. Although an experienced constructor can improvise with tools, most take pride in not abusing them.

### Tool Descriptions and Uses

Specific applications for tools are discussed throughout this chapter. Hand tools are used for so many different applications that they are discussed first, followed by some tips for proper use of power tools.

### Soldering Iron

Soldering is used in nearly every phase of electronic construction so you'll need soldering tools. A soldering tool must be hot enough to do the job and lightweight enough for agility and comfort. A 100-W soldering gun is overkill for printed-circuit work, for example. A temperature-controlled iron works well, although the cost is not justified for occasional projects. Get an iron with a small conical or chisel tip.

Soldering is not like gluing; solder does more than bind metal together and provide an electrically conductive path between them. Soldered metals and the solder combine to form an alloy.

You may need an assortment of soldering irons to do a wide variety of soldering tasks. They range in size from a small 25-W iron for delicate printed-circuit work to larger 100 to 300-W sizes used to solder large surfaces. Several manufacturers also sell soldering guns. Small "pencil" butane torches are also available, with optional soldering-iron tips. A small butane torch is available from the Solder-It Company. This company also sells a soldering kit that contains paste solders (in syringes) for electronics, pot metal and plumbing. See the Address List in the **References** chapter for the address.

Keep soldering tools in good condition by keeping the tips well tinned with solder. Do not run them at full temperature for long periods when not in use. After each period of use, remove the tip and clean off any scale that may have accumulated. Clean an oxidized tip by dipping the hot tip in sal ammoniac (ammonium chloride) and then wiping it clean with a rag. Sal ammoniac is somewhat corrosive, so if you don't wipe the tip thoroughly, it can contaminate electronic soldering.

If a copper tip becomes pitted, file it smooth and bright and then tin it immediately with solder. Modern soldering iron tips are nickel or iron clad and should not be filed.

The secret of good soldering is to use the right amount of heat. Many people who

have not soldered before use too little heat, dabbing at the joint to be soldered and making little solder blobs that cause unintended short circuits.

Solders have different melting points, depending on the ratio of tin to lead. Tin melts at 450°F and lead at 621°F. Solder made from 63% tin and 37% lead melts at 361°F, the lowest melting point for a tin and lead mixture. Called 63-37 (or eutectic), this type of solder also provides the most rapid solid-to-liquid transition and the best stress resistance.

Solders made with different lead/tin ratios have a plastic state at some temperatures. If the solder is deformed while it is in the plastic state, the deformation remains when the solder freezes into the solid state. Any stress or motion applied to "plastic solder" causes a poor solder joint.

60-40 solder has the best wetting qualities. Wetting is the ability to spread rapidly and bond materials uniformly. 60-40 solder also has a low melting point. These factors make it the most commonly used solder in electronics.

Some connections that carry high current can't be made with ordinary tin-lead solder because the heat generated by the current would melt the solder. Automotive starter brushes and transmitter tank circuits are two examples. Silver-bearing solders have higher melting points, and so prevent this problem. High-temperature silver alloys become liquid in the 1100°F to 1200°F range, and a silver-manganese (85-15) alloy requires almost 1800°F.

Because silver dissolves easily in tin, tin bearing solders can leach silver plating from components. This problem can be greatly reduced by partially saturating the tin in the solder with silver or by eliminating the tin. Tin-silver or tin-lead-silver alloys become liquid at temperatures from 430°F for 96.5-3.5 (tin-silver), to 588°F for 1.0-97.5-1.5 (tin-lead-silver). A 15.0-80.0-5.0 alloy of lead-indium-silver melts at 314°F.

Never use acid-core solder for electrical work. It should be used only for plumbing or chassis work. For circuit construction, only use fluxes or solder-flux combinations that are labeled for electronic soldering.

The resin or the acid is a *flux*. Flux removes oxide by suspending it in solution and floating it to the top. Flux is not a cleaning agent! Always clean the work before soldering. Flux is not a part of a soldered connection — it merely aids the soldering process. After soldering, remove any remaining flux. Resin flux can be removed with isopropyl or denatured alcohol. A cotton swab is a good tool for applying the alcohol and scrubbing the

excess flux away. Commercial flux-removal sprays are available at most electronic-part distributors.

The two key factors in quality soldering are time and temperature. Generally, rapid heating is desired, although most unsuccessful solder jobs fail because insufficient heat has been applied. Be careful; if heat is applied too long, the components or PC board can be damaged, the flux may be used up and surface oxidation can become a problem. The soldering-iron tip should be hot enough to readily melt the solder without burning, charring or discoloring components, PC boards or wires. Usually, a tip temperature about 100°F above the solder melting point is about right for mounting components on PC boards. Also, use solder that is sized appropriately for the job. As the cross section of the solder decreases, so does the amount of heat required to melt it. Diameters from 0.025 to 0.040 inches are good for nearly all circuit wiring.

Here's how to make a good solder joint. This description assumes that solder with a flux core is used to solder a typical PC board connection such as an IC pin.

- Prepare the joint. Clean all conductors thoroughly with fine steel wool or a plastic scrubbing pad. Do the circuit board at the beginning of assembly and individual parts such as resistors and capacitors immediately before soldering. Some parts (such as ICs and surface-mount components) cannot be easily cleaned; don't worry unless they're exceptionally dirty.
- Prepare the tool. It should be hot enough to melt solder applied to its tip quickly (half a second when dry, instantly when wet with solder). Apply a little solder directly to the tip so that the surface is shiny. This process is called "tinning" the tool. The solder coating helps conduct heat from the tip to the joint.
- Place the tip in contact with one side of the joint. If you can place the tip on the underside of the joint, do so. With the tool below the joint, convection helps transfer heat to the joint.
- Place the solder against the joint directly opposite the soldering tool. It should melt within a second for normal PC connections, within two seconds for most other connections. If it takes longer to melt, there is not enough heat for the job at hand.
- Keep the tool against the joint until the solder flows freely throughout the joint. When it flows freely, solder tends to form concave shapes between the conductors. With insufficient heat solder does not flow freely; it forms convex

shapes—blobs. Once solder shape changes from convex to concave, remove the tool from the joint.

- Let the joint cool without movement at room temperature. It usually takes no more than a few seconds. If the joint is moved before it is cool, it may take on a dull, satin look that is characteristic of a “cold” solder joint. Reheat cold joints until the solder flows freely and hold them still until cool.
- When the iron is set aside, or if it loses its shiny appearance, wipe away any dirt with a wet cloth or sponge. If it remains dull after cleaning, tin it again.

Overheating a transistor or diode while soldering can cause permanent damage. Use a small heat sink when you solder transistors, diodes or components with plastic parts that can melt. Grip the component lead with a pair of pliers up close to the unit so that the heat is conducted away (be careful — it is easy to damage delicate component leads). A small alligator clip also makes a good heat sink.

Mechanical stress can damage components, too. Mount components so there is no appreciable mechanical strain on the leads.

Soldering to the pins of coil forms or male cable plugs can be difficult. Use a suitable small twist drill to clean the inside of the pin and then tin it with resin-core solder. While it is still liquid, clear the surplus solder from each pin with a whipping motion or by blowing through the pin from the inside of the form or plug. Watch out for flying hot solder! Next, file the nickel plate from the pin tip. Then insert the wire and solder it. After soldering, remove excess solder with a file, if necessary.

When soldering to the pins of plastic coil forms, hold the pin to be soldered with a pair of heavy pliers to form a heat sink. Do not allow the pin to overheat; it will loosen and become misaligned.

In order to remove components, you need to learn the art of desoldering — removing solder from components and PC boards so they can be separated easily. Use commercially made wicking material (braid) to soak up excess solder from a joint. Another useful tool is an air-suction solder remover. Another method is to heat the joint and “flick” the wet solder off. (Watch out for solder splashes!)

Soldering equipment gets *hot*! Be careful. Treat a soldering burn as you would any other. Handling lead or breathing soldering fumes is also hazardous. Observe these precautions to protect yourself and others:

- Properly ventilate the work area. If you can smell fumes, you are breathing them.
- Wash your hands after soldering, especially before handling food.
- Minimize direct contact with flux and flux solvents.

For more information about soldering hazards and the ways to make soldering safer, see “Making Soldering Safer,” by Brian P. Bergeron, MD, NUI N (Mar 1991 *QST*, pp 28-30) and “More on Safer Soldering,” by Gary E. Meyers, K9CZB (Aug 1991 *QST*, p 42).

### **Screwdrivers**

For construction or repair, you need to have an assortment of screwdrivers. Each blade size is designed to fit a specific range of screw-head sizes. Using the wrong size blade usually damages the blade, the screw head or both. You may also need stubby sizes to fit into tight spaces. Right-angle screwdrivers are inexpensive and can get into tight spaces that can’t otherwise be reached.

Electric screwdrivers are relatively inexpensive. If you have a lot of screws to fasten, they can save a lot of time and effort. They come with a wide assortment of screwdriver and nut-driver bits. An electric drill can also function as an electric screwdriver, although it may be heavy and over-powered for some applications.

Keep screwdriver blades in good condition. If a blade becomes broken or worn out, replace the screwdriver. A screwdriver only costs a few dollars; do not use one that is not in perfect condition. Save old screwdrivers to use as pry bars and levers, but use only good ones on screws. Filing a worn blade seldom gives good results.

### **Pliers and Vice Grips**

Pliers and vice grips are used to hold or bend things. They are not wrenches! If pliers are used to remove a nut or bolt, the nut or the pliers is usually damaged. Pliers are not intended for heavy-duty applications. Use a metal brake to bend heavy metal; use a vice to hold a heavy component. To remove a nut, use a wrench or nut driver. There is one exception to this rule of thumb: To remove a nut that is stripped too badly for a wrench, use a pair of pliers, a vice grip or a diagonal cutter to bite into the nut and turn it a bit. If you do this, use an old tool or one dedicated to just this purpose; this technique is not good for the tool. If the pliers jaws or teeth become worn, replace the tool.

### **Wire Cutters**

Wire cutters are primarily used to cut wires or component leads. The choice of diagonal blades (sometimes called

“dikes”) or end-nip blades depends on the application. Diagonal blades are most often used to cut wires, while the end-nip blades are useful to cut off the ends of components that have been soldered into a printed-circuit board. Some delicate components can be damaged by cutting their leads with dikes. Scissors designed to cut wire can be used.

Wire strippers are handy, but you can usually strip wires using a diagonal cutter or a knife. This is not the only use for a knife, so keep an assortment handy.

Do not use wire cutters or strippers on anything other than wire! If you use a cutter to trim a protruding screw head, or cut a hardened-steel spring, you will usually damage the blades.

### **Files**

Files are used for a wide range of tasks. In addition to enlarging holes and slots, they are used to remove burrs, shape metal, wood or plastic and clean some surfaces in preparation for soldering. Files are especially prone to damage from rust and moisture. Keep them in a dry place. The cutting edge of the blades can also become clogged with the material you are removing. Use file brushes (also called file cards) to keep files clean. Most files cannot be sharpened easily, so when the teeth become worn, the file must be replaced. A worn file is sometimes worse than no file at all. At best, a worn file requires more effort.

### **Drill Bits**

Drill bits are made from carbon steel, high-speed steel or carbide. Carbon steel is more common and is usually supplied unless a specific request is made for high-speed bits. Carbon-steel drill bits cost less than high-speed or carbide types; they are sufficient for most equipment construction work. Carbide drill bits last much longer under heavy use. One disadvantage of carbide bits is that they are brittle and break easily, especially if you are using a hand-held power drill.

Twist drills are available in a number of sizes. Those listed in bold type in **Table 25.2** are the most commonly used in construction of amateur equipment. You may not use all of the drills in a standard set, but it is nice to have a complete set on hand. You should also buy several spares of the more common sizes. Although Table 25.2 lists drills down to #54, the series extends to number #80.

### **Specialized Tools**

Most constructors know how to use common tools, such as screwdrivers, wrenches and hammers. Let’s discuss

Fig 25.1 — A nibbling tool is used to remove small sections of sheet metal.

Fig 25.2 — A deburring tool is used to remove the burrs left after drilling a hole.

other tools that are not so common.

A hand nibbling tool is shown in Fig 25.1. Use this tool to remove small "nibbles" of metal. It is easy to use; position the tool where you want to remove metal and squeeze the handle. The tool takes a small bite out of the metal. When you use a nibbler, be careful that you don't remove too much metal, clip the edge of a component mounted to the sheet metal or grab a wire that is routed near the edge of a chassis. Fixing a broken wire is easy, but something to avoid if possible. It is easy to remove metal but nearly impossible to put it back. Do it right the first time!

#### Deburring Tool

A deburring tool is just the thing to remove the sharp edges left on a hole after most drilling or punching operations. See Fig 25.2. Position the tool over the hole as shown and rotate it around the hole edge to

Fig 25.3 — A socket punch is used to easily punch a hole in sheet metal.

remove burrs or rough edges. As an alternative, select a drill bit that is somewhat larger than the hole, position it over the hole, and spin it lightly to remove the burr.

#### Socket Punches

Greenlee is the most widely known of the socket-punch manufacturers. Most socket punches are round, but they do come in other shapes. To use one, drill a pilot hole large enough to clear the bolt that runs through the punch. Then, mount the punch as shown in Fig 25.3, with the cutter on one side of the sheet metal and the socket on the other. Tighten the nut with a wrench until the cutter cuts all the way through the sheet metal.

#### Useful Shop Materials

Small stocks of various materials are used when constructing electronics equipment. Most of these are available from hardware or radio-supply stores. A representative list is shown at the end of Table 25.1.

Small parts, such as machine screws, nuts, washers and soldering lugs can be economically purchased in large quantities (it doesn't pay to buy more than a life-

time supply). For items you don't use often, many radio-supply stores or hardware stores sell small quantities and assortments.

## A DELUXE SOLDERING STATION

The simple tool shown in Figs 25.4 through 25.6 can enhance the usefulness and life of a soldering iron as well as make electronic assembly more convenient. It includes a protective heat sink and a tip-cleaning sponge rigidly attached to a sturdy base for efficient one-handed operation.

Fig 25.4 — A compact assembly of commonly available items, this soldering station makes soldering easier. Miniature toggle switches are used because they are easy to operate.

Fig 25.5 — View of the soldering-station chassis underside with the bottom plate removed. #24 hookup wire is adequate for all connections. Make sure no possibility of a short circuit exists.

Soldering-iron tips and heating elements last longer if operated at a reduced temperature when not being used. Temperature reduction is accomplished by half-wave rectification of the applied ac. D1 conducts during only one-half of the ac cycle. With current flowing only in one direction, only one electrode of the neon bulb glows. Closing S1 short-circuits the diode and applies full power to the soldering iron, igniting both bulb electrodes brightly.

The base for the unit is a 2x6x4-inch (HWD) aluminum chassis (Bud AC-431 or equivalent). A 30- or 40-W soldering iron fits neatly on the chassis top. The holder has two mounting holes in each foot. A sponge tray nests between the feet and the case. In this model, a sardine tin is used for the sponge tray.

The tray and iron holder are secured to the chassis by 6-32 x 1/2-inch pan-head machine screws and nuts, with flat washers under the screw heads (sponge tray) and lock washers under the nuts (chassis underside). One of these nuts fastens a six-lug tie point strip to the chassis bottom. Use the soldering-iron holder base as a template for drilling the chassis and

sponge tray. The floor of the sponge tray must be sealed around the screw heads to prevent moisture from leaking into the electrical components below the chassis. RTV compound was used for this purpose in the unit pictured.

Notice that the soldering iron and the soldering station use separate ac line cords. This ensures that the cord of the soldering iron will be long enough to do useful work. Bushings are used to anchor both cords. If these aren't available, grommets and cable clamps work well. Knotting the cords inside the chassis is a simple technique that normally provides adequate strain relief.

The underchassis assembly is shown in Fig 25.5. The neon bulb is installed in a 3/16-inch-ID grommet. The leads are insulated with spaghetti insulation or heat-shrink tubing to prevent short circuits. If you mount the bulb in a fixture or socket, use a clear lens to ensure that the electrodes are distinctly visible. Install a cover on the bottom of the chassis to prevent accidental contact with the live ac wiring. Stick-on rubber feet prevent the bottom of the unit from scratching your work surface.

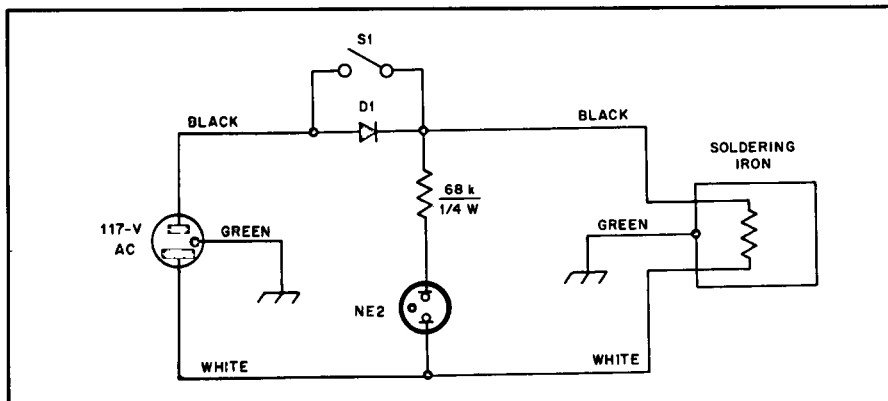

Fig 25.6 — Schematic diagram of the soldering station. D1 is a silicon diode, 1-A, 400-PIV. S1 is a miniature SPST toggle switch rated 3 A at 125 V. This circuit is satisfactory for use with irons having power ratings up to 100 W.

## SOLDERING-IRON TEMPERATURE CONTROL

A temperature control gives greater flexibility than the simple control just described. An incandescent-light dimmer can be used to control the working temperature of the tip. Fig 25.7 shows a temperature control built into an electrical box. A dimmer and a duplex outlet are mounted in the box; the wiring diagram is shown in Fig 25.8. Only one of the two ac outlets is controlled by the dimmer. A jumper on the duplex outlet connects the hot terminals of both outlets together. This jumper must be removed. The hot terminal is narrower than the neutral one and the screw is usually brass. Neutral terminals remain interconnected.

The dimmer shown in Fig 25.7 can be purchased at any hardware or electrical-supply store. The knob is capable of fine control of the soldering temperature.

**Fig 25.7 — An incandescent-light dimmer controls soldering-iron tip temperature. Only one of the duplex outlets is connected through the dimmer.**

**Fig 25.8 — Schematic diagram of the soldering-iron temperature control.**

## Electronic Circuits

Most of the construction projects undertaken by the average amateur involve electronic circuitry. The circuit is the "heart" of most amateur equipment. It might seem obvious, but in order for you to build it, the circuit must work! Don't always assume that a "cookbook" circuit that appears in an applications note or electronics magazine is flawless. These are sometimes design examples that have not always been thoroughly debugged. Many home-construction projects are "one-time" deals; the author has put one together and it worked. In some cases, component tolerances or minor layout changes might make it difficult to get a second unit working.

### Protecting Components

You need to take steps to protect the electronic and mechanical components you use in circuit construction. Some components can be damaged by rough handling. Dropping a  $\frac{1}{4}$ -W resistor causes no harm, but dropping a vacuum tube or other delicate subassemblies usually causes damage.

Some components are easily damaged by heat. Some of the chemicals used to clean electronic components (such as flux removers, degreasers or control-lubrication sprays) can damage plastic. Check them for safety before you use them.

### Electrostatic Discharge

Some components, especially high-impedance components such as FETs and CMOS gates, can be damaged by electro-

static discharge (ESD). Protect these parts from static charges. Most people are familiar with the static charge that builds up when one walks across a carpet then touches a metal object; the resultant spark can be quite lively. Walking across a carpet on a dry day can generate 35 kV! A worker sitting at a bench can generate voltages up to 6 kV, depending on conditions, such as when relative humidity is less than 20%.

You don't need this much voltage to damage a sensitive electronic component; damage can occur with as little as 30 V. The damage is not always catastrophic. A MOSFET can become noisy, or lose gain; an IC can suffer damage that causes early failure. To prevent this kind of damage, you need to take some precautions.

The energy from a spark can travel inside a piece of equipment to effect internal components. Protection of sensitive electronic components involves the prevention of static build-up together with the removal of any existing charges by dissipating any energy that does build up.

Several techniques can be used to minimize static build-up. First, remove any carpet in your work areas. You can replace it with special antistatic carpet, but this is expensive. It's less expensive to treat the carpet with antistatic spray, which is available from Chemtronics, GC Thorsen and other lines carried by electronics wholesalers.

Even the choice of clothing you wear can affect the amount of ESD. Polyester

has a much greater ESD potential than cotton.

Many builders who have their workbench on a concrete floor use a rubber mat to minimize the risk of electric shocks from the ac line. Unfortunately, the rubber mat increases the risk of ESD. An antistatic rubber mat can serve both purposes.

Many components are shipped in anti-static packaging. Leave components in their conductive packaging. Other components, notably MOSFETs, are shipped with a small metal ring that temporarily shorts all of the leads together. Leave this ring in place until the device is fully installed in the circuit.

These precautions help reduce the build-up of electrostatic charges. Other techniques offer a slow discharge path for the charges or keep the components and the operator handling them at the same ground potential.

One of the best techniques is to connect the operator and the devices being handled to earth ground, or a common reference point. It is not a good idea to directly ground an operator working on electronic equipment, though; the risk of shock is too great. If the operator is grounded through a high-value resistor, ESD protection is still offered but there is no risk of shock.

The operator is usually grounded through a conductive wrist strap. 3M makes a grounding wrist band. This wrist band is equipped with a snap-on ground lead. A 1-M $\Omega$  resistor is built into the snap

**Fig 25.9**—A work station that has been set up to minimize ESD features (1) a grounded dissipative work mat and (2) a wrist strap that (3) grounds the worker through high resistance.

**Fig 25.10** — Schematic diagram of the audio amplifier used as a design example of various construction techniques.

**Fig 25.11** — The example audio amplifier of Fig 25.10 built using ground-plane construction.

of the strap to protect the user should a live circuit be contacted. Build a similar resistor into any homemade ground strap.

The devices and equipment being

handled are also grounded, by working on a charge-dissipating mat that is connected to ground. The mat should be an insulator that has been impregnated with a resistance material. Suitable mats and wrist straps are made by 3M, GC Electronics and others; they are available from most electronics supply houses. **Fig 25.9** shows a typical ESD-safe work station.

The work area should also be grounded, directly or through a conductive mat. Use a soldering iron with a grounded tip to solder sensitive components. Most irons that have three-wire power cords are properly grounded. When soldering static-sensitive devices, use two or three jumpers to ground you, the work and the iron. If the iron does not have a ground wire in the power cord, clip a jumper from the metal part of the iron near the handle to the metal box that houses the temperature control. Another jumper connects the box to the work. Finally, a jumper goes from the box to an elastic wrist band for static grounding.

Use antistatic bags to transport susceptible components or equipment. Keep your workbench free of objects such as paper, plastic and other static-generating items. Use conductive containers with a dissipative surface coating for equipment storage.

All of the antistatic products described above are available from Newark Electronics and other suppliers. See the Address List in the **References** chapter.

## Electronics Construction Techniques

Several different point-to-point wiring techniques or printed-circuit boards (PC

boards) can be used to construct electronic circuits. Most circuit projects use a combination of techniques. The selection of techniques depends on many different factors and builder preferences.

The simple audio amplifier shown in **Fig 25.10** will be built using various point-to-point or PC-board techniques. This shows how the different construction methods are applied to a typical circuit.

## Point-to-Point Techniques

Point-to-point techniques include all circuit construction techniques that rely on tie points and wiring, or component leads, to build a circuit. This is the technique used in most home-brew construction projects. It is sometimes used in commercial construction, such as old vacuum-tube receivers and modern tube amplifiers.

Point-to-point is also used to connect the “off-board” components used in a printed-circuit project. It can be used to interconnect the various modules and printed-circuit boards used in more complex electronic systems. Most pieces of electronic equipment have at least some point-to-point wiring.

## Ground-Plane Construction

A point-to-point construction technique that uses the leads of the components as tie points for electrical connections is known as “ground-plane construction,” “dead-bug” or “ugly construction.” (The term “ugly construction” was coined by Wes Hayward, W7ZOI.) “Dead-bug construction” gets its name from the appearance of an IC with its leads sticking up in the air. In most cases, this technique uses copper-clad circuit-board material as a foundation and ground plane on which to build a circuit using point-to-point wiring, so in this chapter it is called “ground-plane construction.” An example is shown in **Fig 25.11**.

Ground-plane construction is quick and simple: You build the circuit on an unetched piece of copper-clad circuit board. Wherever a component connects to ground, you solder it to the copper board. Ungrounded connections between components are made point-to-point. Once you learn how to build with a ground-plane board, you can grab a piece of circuit board and start building any time you see an interesting circuit.

A PC board has strict size limits; the components must fit in the space allotted. Ground-plane construction is more flexible; it allows you to use the parts on hand. The circuit can be changed easily — a big help when you are experimenting. The greatest virtue of ground-plane construction is that it is fast.

Ground-plane construction is some-

thing like model building, connecting parts using solder almost—but not exactly—like glue. In ground-plane construction you build the circuit directly from the schematic, so it can help you get familiar with a circuit and how it works. You can build subsections of a large circuit on small ground-plane modules and string them together into a larger design.

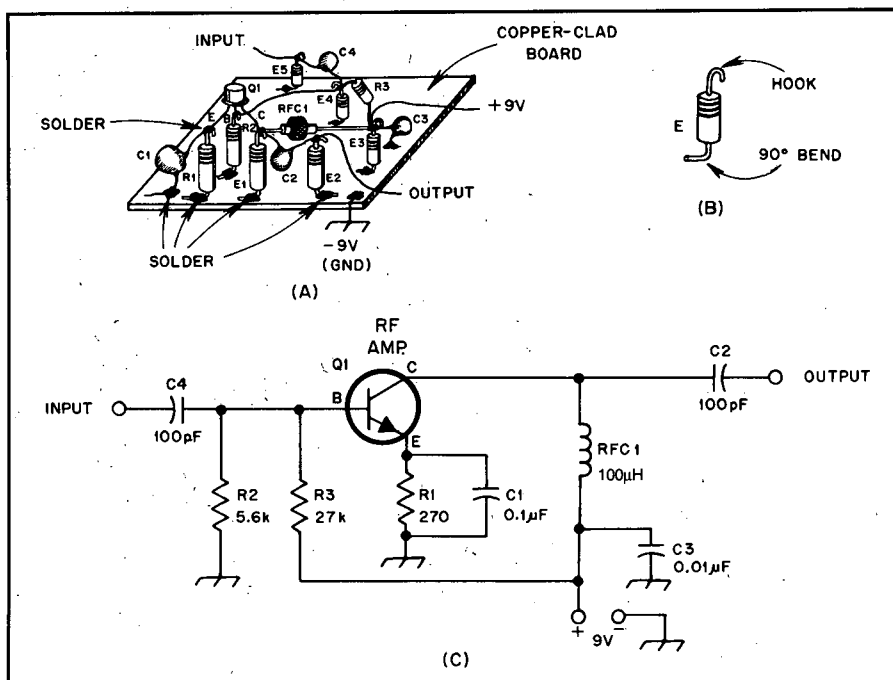

Circuit connections are made directly, minimizing component lead length. Short lead lengths and a low-impedance ground conductor help prevent circuit instability. There is usually less intercomponent capacitive coupling than would be found between PC-board traces, so it is often better than PC-board construction for RF, high-gain or sensitive circuits.

Use circuit components to support other circuit components. Start by mounting one component onto the ground plane, building from there. There is really only one two-handed technique to mount a component to the ground plane. Bend one of the component leads at a 90° angle, then trim off the excess. Solder a blob of solder to the board surface, perhaps about 0.1 inch in diameter, leaving a small dome of solder. Using one hand, hold the component in place on top of the soldered spot and reheat the component and the solder. It should flow nicely, soldering the component securely. Remove the iron tip and hold the component perfectly still until the solder cools. You can then make connections to the first part.

Connections should be mechanically secure before soldering. Bend a small hook in the lead of a component, then “crimp” it to the next component(s). Do not rely only on the solder connections to provide mechanical strength; sooner or later one of these connections will fail, resulting in a dead circuit.

In most cases, each circuit has enough grounded components to support all of the components in the circuit. This is not always possible, however. In some circuits, high-value resistors can be used as stand-off insulators. One resistor lead is soldered to the copper ground plane, the other lead is used as a circuit connection point. You can use  $\frac{1}{4}$ - or  $\frac{1}{2}$ -W resistors in values from 1 to 10 M $\Omega$ . Such high-value resistors permit almost no current to flow, and in low-impedance circuits they act more like insulators than resistors. As a rule of thumb, resistors used as stand-off insulators should have a value that is at least 10 times the circuit impedance at that circuit point.

Fig 25.12A shows how to use the stand-off technique to wire the circuit shown at Fig 25.12C. Fig 25.12B shows how the resistor leads are bent before the stand-off component is soldered to the ground plane.

**Fig 25.12 — Pictorial view of a circuit board that uses ground-plane construction is shown at A. A close-up view of one of the standoff resistors is shown at B. Note how the leads are bent. The schematic diagram at C shows the circuit displayed at A.**

Components E1 through E5 are resistors that are used as stand-off insulators. They do not appear in the schematic diagram. The base circuitry at Q1 of Fig 25.12A has been stretched out to reduce clutter in the drawing. In a practical circuit, all of the signal leads should be kept as short as possible. E4 would, therefore, be placed much closer to Q1 than the drawing indicates.

No stand-off posts are required near R1 and R2 of Fig 25.12. These two resistors serve two purposes: They are not only the normal circuit resistances, but function as stand-off posts as well. Follow this practice wherever a capacitor or resistor can be employed in the dual role.

#### Wired Traces — the Lazy PC Board

If you already have a PC-board design, but don't want to copy the entire circuit—or you don't want to make a double-sided PC board—then the easiest construction technique is to use a bare board (or perfboard) and hard-wire the traces.

Drill the necessary holes in a piece of single-sided board, remove the copper ground plane from around the holes, and then wire up the back using component leads and bits of wire instead of etched traces (Fig 25.13).

To transfer an existing board layout, make a 1:1 photocopy and tape it to your piece of PC board. Prick through the holes with an automatic (one-handed) center

**Fig 25.13 — The audio amplifier built using wired-traces construction.**

punch or by firm pressure with a sharp scribe, remove the photocopy and drill all

**Fig 25.15 — The audio amplifier built using terminal-and-wire construction.**

**Fig 25.14 — The audio amplifier built on perforated board. Top view at A; bottom view at B.**

the holes. Holes for ground leads are optional — you generally get a better RF ground by bending the component lead flat to the board and soldering it down. Remove the copper around the rest of the holes by pressing a drill bit lightly against the hole and twisting it between your fingers. A drill press can also be used, but either way, don't remove too much board material. Then wire up the circuit beneath the board. The results look very neat and tidy — from the top, at least!

Circuits that contain components originally designed for PC-board mounting are good candidates for this technique. Wired

**Fig 25.16 — The audio amplifier built on a solderless prototyping board.**

traces would also be suitable for circuits involving multipin RF ICs, double-balanced mixers and similar components. To bypass the pins of these components to ground, connect a miniature ceramic capacitor on the bottom of the board directly from the bypassed pin to the ground plane.

A wired-trace board is fairly sturdy, even though many of the components are only held in by their bent leads and blobs of solder. A drop of cyanoacrylate "super glue" can hold down any larger components, components with fragile leads or any long leads or wires that might move.

### **Perforated Construction Board**

A simple approach to circuit building uses a perforated board (perfboard). Perfboard is available with many different hole patterns. Choose the one that suits your needs. Perfboard is usually unclad, although it is made with pads that facilitate soldering.

Circuit construction on perforated board is easy. Start by placing the compo-

nents loosely on the board and moving them around until a satisfactory layout is obtained. Most of the construction techniques described in this chapter can be applied to perfboard. The audio amplifier of Fig 25.10 is shown constructed with this technique in Fig 25.14.

Perfboard and accessories are widely available. Accessories include mounting hardware and a variety of connection terminals for solder and solderless construction.

### **Terminal and Wire**

A perfboard is usually used for this technique (Fig 25.15). Push terminals are inserted into the hole in a perfboard. Components can then be easily soldered to the terminals. As an alternative, drill holes into a bare or copper-clad board wherever they are needed. The components are usually mounted on one side of the board and wires are soldered to the bottom of the board, acting as wired PC-board "traces." If a component has a reasonably rigid lead to which you can attach other components, use that instead of a push terminal, a modification of the ground-plane construction technique.

If you are using a bare board to provide a ground plane, drill holes for your terminals with a high-speed PC-board drill and drill press. Mark the position of the hole with a center punch to prevent the drill from skidding. The hole should provide a snug fit for the push terminal.

Mount RF components on top of the board, keeping the dc components and much of the interconnecting wiring underneath. Make dc feed-through connections with terminals having bypass capacitors on top of the board. Use small solder-in feedthrough capacitors for more critical applications.

### **Solderless Prototype Board**

One construction alternative that works well for audio and digital circuits is the solderless prototype board (protoboard), shown in Fig 25.16. It is usually not suitable for RF circuits.

A protoboard has rows of holes with spring-loaded metal strips inside the board. Circuit components and hookup wire are inserted into the holes, making contact with the metal strips. Components that are inserted into the same row are connected together. Component and interconnection changes are easy to make.

Protoboards have some minor disadvantages. The boards are not good for building RF circuits; the metal strips add too much stray capacitance to the circuit. Large component leads can deform the metal strips.

**Fig 25.17 — The audio amplifier built using wire-wrap techniques.**

### Wire Wrap

Wire-wrap techniques can be used to quickly construct a circuit without solder. Low- and medium-speed digital circuits are often assembled on a wire-wrap board. The technique is not limited to digital circuits, however. **Fig 25.17** shows the audio amplifier built using wire wrap. Circuit changes are easy to make, yet the method is suitable for permanent assemblies.

Wire wrap is done by wrapping a wire around a small square post to make each connection. A wrapping tool resembles a thick pencil. Electric wire-wrap guns are convenient when many connections must be made. The wire is almost always #30 wire with thin insulation. Two wire-wrap methods are used: the standard and the modified wrap (**Fig 25.18**). The modified wrap is more secure. The wrap-post terminals are square (wire wrap works only on posts with sharp corners). They should be long enough for at least two connections. **Fig 25.18** and **Fig 25.19** show proper and improper wire-wrap techniques. Mount

**Fig 25.18 — Wire-wrap connections. Standard wrap is shown at A; modified wrap at B.**

**Fig 25.19 — Improper wire-wrap connections. Insufficient insulation for modified wrap is shown at A; a spiral wrap at B, where there is too much space between turns; an open wrap at C, where one or more turns are improperly spaced and an overwrap at D, where the turns overlap on one or more turns.**

small components on an IC header plug. Insert the header into a wire-wrap IC socket as shown in **Fig 25.17**. The large capacitor in that figure has its leads soldered directly to wire-wrap posts.

### Surface Mounting

Surface mounting is not new — it was an established ground-plane and professional technique for years before its appearance in consumer and amateur electronics. This technique is particularly suitable for PC-board construction, although it can be applied to many other construction techniques. Surface-mounted components take up very little space on a PC board.

Modern automated manufacturing techniques and surface-mount technology have evolved together; most modern ICs

**Fig 25.20 — A modern surface-mount IC, properly installed on a PC board.**

**Fig 25.21 — A PC-board etched with copper "islands" for surface mounting of a standard DIP IC.**

are being made specifically for this technique. **Fig 25.20** shows a surface-mount IC soldered onto a board.

Chip resistors and capacitors are common in UHF and microwave designs. Chip devices have low stray inductance and capacitance, making them excellent components to use in this frequency range. Other components, such as transistors and diode arrays are also available in this space-saving format.

Surface-mount techniques are not limited to "surface-mount" ICs, however. This technique can be used to mount standard resistors, capacitors or ICs.

Two different ground-plane construction techniques work well for surface mounting components. One method is to cut out or etch small insulated islands in the PC board (see **Fig 25.21**). This works with either single- or double-sided board. Cut out the islands with a small hobby knife, making parallel cuts spaced as needed. Peel away the copper with the point of a hot soldering iron. An alternative is to use a hand-held hobbyist grinder with a cutting bit. You can also design a surface-mount PC-board pattern.

The second method of surface mounting is shown in **Fig 25.22**. Cut small patches of single-sided board and superglue them onto the copper ground plane. Although very effective, this technique is tedious for all but the simplest circuits. Don't glue your fingers to the PC board. Keep the glue solvent (usually acetone or nail-polish remover) nearby!

The surface-mount ICs used in industry are not easy for experimenters to use. They have tiny pins designed for precision PC boards. Most hams avoid these in homebrew designs. Sooner or later, you may need to replace one, though. If you do, don't try to get the old IC out in one piece! This will damage the IC beyond use anyway, and may damage the PC board in the process.

**Fig 25.22** — A PC board with glued copper traces for surface mounting of a standard DIP IC.

Although it requires a delicate touch and small tools, it's possible to change a surface mount IC at home. To remove the old one, use small, sharp wire cutters to cut the IC pins flush with the IC. This usually leaves just enough old pin to grab with a tiny pair of needle-nose pliers or a hemostat. Heat the soldered connection with a small iron and use the pliers to gently pull the pin from the PC board.

To install a new part, apply a small blob of solder to one of the pads. Position the IC on the PC board and press it down while applying heat to the pin over the solder blob. With only that one pin soldered, inspect the position of each other pin relative to its pad. Reheat the first pin and reposition the part until all pins are in place. Then solder the remaining pins to their pads. Watch out for solder bridges. They are easy to make on traces with such small spacing. When you are done, inspect your work carefully.

Small "chip" surface-mount components are a bit trickier because they are too small to hold safely during soldering. Special care must be used when soldering chip components. **Fig 25.23** illustrates a good technique. All surfaces should be clean and lightly tinned before you solder the chip. Position the chip in place and hold it down with a toothpick. Do not use a screwdriver or tweezers, because the metal can easily damage the ceramic base of the component. Lay the chisel tip of a 15- to 20-W soldering pencil on the surface to which the chip is to be soldered, with the tip of the chisel just touching the chip component.

Touch and flow a minimum amount of solder between the chip and the soldering-pencil tip and pull the tip away at a low

angle to the surface. Repeat the procedure on the other side of the chip. If you don't use too much heat while soldering the second end, you may not have to hold it in place. **Fig 25.23C** shows how the connection should look when done. Inspect the solder and chip with a magnifier. The solder should have flowed properly and there should be no fractures or cracks. Don't overheat the chip or the metallization may separate from the ceramic and ruin the component. It requires a little practice, but the technique can be mastered.

## Printed-Circuit Boards

Many builders prefer the neatness and miniaturization made possible by the use of etched printed-circuit boards (PC boards). Once designed, a PC board is easily duplicated, making PC boards ideal for group projects. To make a PC board, resist material is applied to a copper-clad bare PC board, which is then immersed into an acid etching bath to remove selected areas of copper. In a finished board, the conductive copper is formed into a pattern of conductors or "traces" that form the actual wiring of the circuit.

### PC Board Stock

PC board stock consists of a sheet made from insulating material, usually glass epoxy or phenolic, coated with conductive copper. Copper-clad stock is manufactured with phenolic, FR-4 fiberglass and Teflon base materials in thicknesses up to  $\frac{1}{8}$  inch. The copper thickness varies. It is usually plated from 1 to 2 oz per square foot of bare stock.

### Resists

Resist is a material that is applied to a PC board to prevent the acid etchant from eating away the copper on those areas of the board that are to be used as conductors. There are several different types of resist materials, both commercial and home brew. When resist is applied to those areas of the board that are to remain as copper traces, it "resists" the acid action of the etchant.

The PC board stock must be clean before any resist is applied. This is discussed later in the chapter. After you have applied resist, by whatever means, protect the board by handling it only at its edges. Do not let it get scraped. Etch the board as soon as possible, to minimize the likelihood of oxidation, moisture or oils contaminating the resist or bare board.

### Tape

To make a single PC board, Scotch, adhesive or masking tape, securely applied, makes a good resist. (Don't use drafting tape; its glue may be too weak to

**Fig 25.23** — A typical chip capacitor is shown at A. The proper technique for holding and soldering the chip is shown at B. At C, the final appearance of the component in the circuit. Check for good solder flow, no metallization separation and no cracks or fractures in the ceramic.

hold in the etching bath.) Apply the tape to the entire board, transfer the circuit pattern by means of carbon paper, then cut out and remove the sections of tape where the copper is to be etched away. An X-acto hobby knife is excellent for this purpose.

### **Resist Pens**

Several electronics suppliers sell resist pens. Use a resist pen to draw PC-board artwork directly onto a bare board. Commercially available resist pens work well. Several types of permanent markers also function as resist, especially the "Sharpie" brand. They come in fine-point and regular sizes; keep two of each on hand.

### **Paint**

Some paints are good resists. Exterior enamel works well. Nail polish is also good, although it tends to dry quickly so you must work fast. Paint the pattern onto the copper surface of the board to be etched. Use an artist's brush to duplicate the PC board pattern onto bare PC-board stock. Tape a piece of carbon paper to the PC-board stock. Tape the PC-board pattern to the carbon paper. Trace over the original layout with a ballpoint pen. The carbon paper transfers the outline of the pattern onto the bare board. Fill in the outline with the resist paint. After paint has been applied, allow it to dry thoroughly before etching.

### **Rub-On Transfer**

Several companies, (Kepro Circuit Systems, DATAK Corp, GC Electronics) produce rub-on transfer material that can also be used as resist. Patterns are made with various width traces and for most components, including ICs. As the name implies, the pad or trace is positioned on the bare board and rubbed to adhere to the board.

### **Etchant**

Etchant is an acid solution that is designed to remove the unwanted copper areas on PC-board stock, leaving other areas to function as conductors. Almost any strong acid bath can serve as an etchant, but some acids are too strong to be safe for general use. Two different etchants are commonly used to fabricate prototype PC boards: ammonium persulphate and ferric chloride. The latter is the more common of the two.

Ferric chloride etchant is usually sold ready-mixed. It is made from one part ferric chloride crystals and two parts water, by volume. No catalyst is required.

Etchant solutions become exhausted as they are used. Keep a supply on hand. Dispose of the used solution safely; follow the instructions of your local environmental protection authority.

Most etchants work better if they are hot. A board that takes 45 minutes to etch at room temperature will take only a few minutes if the etchant is hot. Use a heat lamp to warm the etchant to the desired temperature. A darkroom thermometer is handy for monitoring the temperature of the bath.

Be careful! Do not heat your etchant above the recommended temperature, typically 160°F. If it gets too hot, it will probably damage the resist. Hot or boiling etchant is also a safety hazard.

Insert the board to be etched into the solution and agitate it continuously to keep fresh chemicals near the board surface. This speeds up the etching process. Normally, the circuit board should be placed in the bath with the copper side facing up.

After the etching process is completed, remove the board from the tray and wash it thoroughly with water. Use medium-grade steel wool to rub off the resist.

**WARNING:** Use a glass or other nonreactive container to hold etching chemicals. Most etchants will react with a metal container. Etchant is caustic and can burn eyes or skin easily. Use rubber gloves and wear old clothing, or a lab smock, when working with any chemicals. If you get some on your skin, wash it with soap and cold water. Wear safety goggles (the kind that fit snugly on your face) when working with any dangerous chemicals. Read the safety labels and follow them carefully. If you get etchant in your eyes, wash immediately with large amounts of cool water and seek immediate medical help. Even a small chemical burn on your eye can develop into a serious problem.

### **Planning and Layout**

A PC board can be a real convenience. If you want to build a project and a ready-made PC board is available, you can assemble the project quickly and expect it to work. This is true because someone else has done most of the real work involved—designing the PC board layout and fixing any "bugs" caused by intertrace capacitive coupling, ground loops and similar problems. In most cases, if a ready-made board is not available, ground-plane construction is a lot less work than designing, debugging and then making a PC board.

A later section of this chapter explains how to turn a schematic into a working circuit. It is not as simple as laying out the PC board just like the circuit is drawn on the schematic. Read that section before you design a PC board.

### **Rough Layout**

Start by drawing a rough scale pictorial diagram of the layout. Draw the intercon-

necting leads to represent the traces that are needed on the board. Rearrange the layout as necessary to find an arrangement that completes all of the circuit traces with a minimum number of jumper-wire connections. In some cases, however, it is not possible to complete a design without at least a few jumpers.

### **Layout**

After you have completed a rough layout, redraw the physical layout on a grid. Graph paper works well for this. Most IC pins are on 0.1-inch centers. Use graph paper that has 10 lines per inch to draw artwork at 1:1 and estimate the distance halfway between lines for 0.05-inch spacing. Drafting templates are helpful in the layout stage. Local drafting-supply stores should be able to supply them. The templates usually come in either full-scale or twice normal size.

To lay out a double-sided board, ensure that the lines on both sides of the paper line up (hold the paper up to the light). You can then use each side of the paper for each side of the board.

When using graph paper for a PC-board layout, include bolt holes, notches for wires and other mechanical considerations. Fit the circuit into and around these, maintaining clearance between parts.

Most modern components have leads on 0.1-inch centers. The rows of dual-inline-package (DIP) IC pins are spaced 0.3 or 0.4 inch. Measure the spacing for other components. Transfer the dimensions to the graph paper. It is useful to draw a schematic symbol of the component onto the layout.

Most IC specification sheets show a top view of the pin locations. If you are designing the "foil" side of a PC board, be sure to invert the pin out.

Draw the traces and pads the way they will look. Using dots and lines is confusing. It's okay to connect more than one lead per pad, or run a lead through a pad, although using more than two creates a complicated layout. In that case, there may be problems with solder bridges that form short circuits. Traces can run under some components; it is possible to put two or three traces between 0.4-inch centers for a 1/4-W resistor, for example.

Leave power-supply and other dc paths for last. These can usually run just about anywhere, and jumper wires are fine for these noncritical paths.

Do not use traces less than 0.010 inch (10 mil) wide. If 1-oz stock is used, a 10-mil trace can safely carry up to 500 mA. To carry higher current, increase the width of the traces in proportion. (A trace should

be 0.200 inch to carry 10 A, for example.) Allow 0.1 inch between traces for each kilovolt in the circuit.

When doing a double-sided board, use pads on both sides of the board to connect traces through the board. Home-brew PC boards do not use plated-through holes (a manufacturing technique that has copper and tin plating inside all of the holes to form electrical connections). Use a through hole and solder the associated component to both sides of the board. Make other through-hole connections with a small piece of bus wire providing the connection through the board; solder it on both sides. This serves the same purpose as the plated-through holes found in commercially manufactured boards.

After you have planned the physical design of the board, decide the best way to complete the design. For one or two simple boards, draw the design directly onto the board, using a resist pen, paint or rub-on resist materials. To transfer the design to the PC board, draw light, accurate pencil lines at 0.1- or 0.05-inch centers on the PC board. Draw both horizontal and vertical lines, forming a grid. You only need lines on one side. For single-sided boards, use this grid to transfer the layout directly onto the board surface. To make drilling easier, use a center punch to punch the centers of holes accurately. Do this before applying the resist so the grid is visible.

When drawing a pad with plenty of room around it, use a pad about 0.05 to 0.1 inch in diameter. For ICs, or other close quarters, make the pad as small as 0.03 inch or so. A "ring" that is too narrow invites soldering problems; the copper may delaminate from the heat. Pads need not be round. It's okay to shave one or more edges if necessary, to allow a trace to pass nearby.

Draw the traces next. A drafting triangle can help. It should be spaced about 0.1 inch above the table, to avoid smudging the artwork. Use a 9-inch or larger triangle, with a rubber grommet taped to each

corner (to hold it off the table). Select a sturdy triangle that doesn't bend easily.

Align the triangle with the grid lines by eye and make straight, even traces similar to the layout drawing. The triangle can help with angled lines, too. Practice on a few pieces of scrap board.

Make sure that the resist adheres well to the PC board. Most problems can be seen by eye; there can be weak areas or bare spots. If necessary, touch up problems with additional resist. If the board is not clean the resist will not adhere properly. If necessary, remove the resist, clean the board and start from the beginning.

Discard troublesome pens. Resist pens dry out quickly. Keep a few on hand, switch back and forth and put the cap back on each for a bit to give the pen a chance to recover.

Once all of the artwork on the board is drawn, check it against the original artwork. It is easy to leave out a trace. It is not easy to put copper back after a board is etched. In a pinch, replace the missing trace with a small wire.

Applied resist takes about an hour to dry at room temperature. Fifteen minutes in a 200°F oven is also adequate.

Special techniques are used to make double-sided PC boards. See the section on double-sided boards for a description.

### **Making a PC Board**

Several techniques can be used to make PC boards. They usually start with a PC-board "pattern" or artwork. All of the techniques have one thing in common: this pattern needs to be transferred to the copper surface of the PC board. Unwanted copper is then removed by chemical or mechanical means.

Most variations in PC-board manufacturing technique involve differences in resist or etchant materials or techniques.

### **Cut the Board to Size**

No matter what technique you use, you should determine the required size of the PC board, then cut the board to size. Trimming off excess PC-board material can be difficult after the components are installed.

### **Board Preparation**

The bare (unetched) PC-board stock should be clean and dry before any resist is applied. (This is not necessary if you are using stock that has been treated with presensitized photoresist.) Wear rubber gloves when working with the stock to avoid getting fingerprints on the copper surface. Clean the board with soap and water, then scrub the board with #000 steel wool. Rinse the board thoroughly then dry it with a clean, lint-free cloth. Keep the board clean and free of fingerprints or for-

eign substances throughout the entire manufacturing process.

### **No-Etch PC Boards**

The simplest way to make PC boards is to mechanically remove the unwanted copper. Use a grinding tool, such as the Moto-Tool manufactured by the Dremel Company (available at most hardware or hobby stores). Another technique is to score the copper with a strong, sharp knife, then remove unwanted copper by heating it with a soldering iron and lifting it off with a knife while it is still hot. This technique requires some practice and is not very accurate. It often fails with thin traces, so use it only for simple designs.

### **Photographic Process**

Many magazine articles feature printed-circuit layouts. Some of these patterns are difficult to duplicate accurately by hand. A photographic process is the most efficient way to transfer a layout from a magazine page to a circuit board.

The resist ink, tape or dry-transfer processes can be time consuming and tedious for very complex circuit boards. As an alternative, consider the photo process. Not only does the accuracy improve, you need not trace the circuit pattern yourself!

A copper board coated with a light-sensitive chemical is at the heart of the photographic process. In a sense, this board becomes your photographic film.

Make a contact print of the desired pattern by transferring the printed-circuit artwork to special copy film. This film is attached to the copper side of the board and both are exposed to intense light. The areas of the board that are exposed to the light—those areas not shielded by the black portions of the artwork—undergo a chemical change. This creates a transparent image of the artwork on the copper surface.

Develop the PC board, using techniques and chemicals specified by the manufacturer. After the board is developed, etch it to remove the copper from all areas of the board that were exposed to the light. The result is a PC board that looks like it was made in a factory.

Kepro and GC Thorsen both sell materials and supplies for all types of PC-board manufacturing. Radio Shack also sells PC-board materials. See Fig 25.24. If you're looking for printed-circuit board kits, chemicals, tools and other materials, contact Ocean State Electronics. They carry products by Kepro, GC Thorsen, Datak and the Meadowlake Corporation.

### **Iron-On Resist**

One company that makes an iron-on resist is the Meadowlake Corporation.

**Fig 25.24 — PC-board materials are available from several sources. This kit is from Radio Shack.**

## Double-Sided PC Boards — by Hand!

Forget those nightmares about expensive photoresists that didn't work; forget that business of fifty bucks a board! You don't need computer-aided design to make a double-sided PC board; just improve on the basics, and keep it simple. Anyone can make low-cost double-sided boards with traces down to 0.020 inch, with perfect front-to-back hole registration.

To make a double-sided board, drill the holes before applying the resist artwork; that is the only way to assure good front-to-back registration. The artwork on both sides can then be properly positioned to the holes. PC-board drilling was discussed earlier in the text.

After you have drilled the board, clean its surface thoroughly. After that, wear clean rubber or cotton gloves to keep it clean. One fingerprint can really mess up the application of resist or the etchant.

**Fig A —** Make a permanent marker into a specialized PC-board drawing tool. Simply press the marker point into a drilled hole to form a modified point as shown. More pressure produces a wider shoulder that makes larger pads on the PC board.

Tape the board to your work surface, making sure it can't move around. Transfer the artwork from your layout grid to the PC board, drawing by hand with a resist pen.

Allot enough time to finish at least one side of the artwork in one sitting. Start with the pads. To make a handy pad-drawing tool, press the tip of a regular-size Sharpie into one of the drilled PC-board holes. This "smoothes" the tip into the shape of the hole, leaving a flat shoulder to draw the pad. See **Fig A**. The diameter of the pad is determined by how hard the pen is pressed; pressing too hard forms a pad that is way too large for most applications. Practice on scrap board first. Use this modified pen to fill in all the holes and draw the pads at the same time. Use an unmodified resist pen to draw all of the traces and to touch up any voids or weak areas in the pads. For the rest of the drawing, the procedure described for single-sided boards applies to double-sided boards, too.

After the resist is applied to the first side, carefully draw the second side. Inspect the board thoroughly; you may have scratched or smudged the first side while you were drawing the second.

Etching a double-sided board is not much different than etching a single-sided board, except that you must ensure that the etchant is able to reach both sides of the board. If you dunk the board in and out of the etchant solution, both sides are exposed to the etchant. If you use a tray, put some spacers on the bottom and rest the board on the spacers. (The spacers must be put on the board edges, not where you want to actually etch.) This ensures that etchant gets to both sides. If you use this method, turn the board over once or twice during the process. — *Dave Reynolds, KE7QF*

### Or Photo-Etched

You can also make double-sided boards at home without drawing the

layout by hand. This procedure can't produce results to match the finest professionally made double-sided boards, but it can make boards that are good enough for many moderately complex projects.

Start with the same sort of artwork used for single-sided boards, but leave a margin for taping at one edge. It is critical that the patterns for the two sides are accurately sized. The chief limiting factor in this technique is the requirement that matching pads on the two sides are positioned correctly. Not only must the two sides match each other, but they must also be the correct size for the parts in the project. Slight reproduction errors can accumulate to major problems in the length of a 40-pin DIP IC. One good tool to achieve this requirement is a photocopy machine that can make reductions and enlargements in 1% steps. Perform a few experiments to arrive at settings that yield accurately sized patterns.

Choose two holes at opposite corners of the etching patterns. Tape one of the two patterns to one side of the PC board. Choose some small wire and a drill bit that closely matches the wire diameter. For example, #20 enameled wire is a close match for a #62 or a #65 drill, depending on the thickness of the wire's enamel coating. Drill through the pattern and the board at the two chosen holes. Drill the chosen holes through the second pattern. Place two pieces of the wire through the PC board and slide the second pattern down these wire "pins" to locate the pattern on the board. Tape the second pattern in position and remove the pins. From this point on, expose and process each side of the board as if it were a single-sided board, but take care when exposing each side to keep the reverse side protected from light.

— *Bob Schetgen, KU7G*

Their products make an artwork positive using a standard photocopier. A clothes iron transfers the printed resist pattern to the bare PC board.

Some experimenters have reported satisfactory results using standard photocopier paper or the output from a laser

printer. Apparently the toner makes a reasonable resist. Note that the artwork for this method must be reversed with respect to a normal etching pattern because the print must be placed with the toner against the copper.

To transfer the resist pattern onto the

board, place the pattern on the board (image side toward the copper), then firmly press a hot iron onto the entire surface. Use plenty of heat and even pressure. This melts the resist, which then sticks to the bare PC board. This is not a perfect process; there will probably be bad areas on the resist. The

amount of heat, the cleanliness of the bare board and the "skill" of the operator may affect the outcome.

The key to making high quality boards with the photocopy techniques is to be good at retouching the transferred resist. Fortunately, the problems are usually easy to retouch, if you have a bit of patience. A resist pen does a good job of reinforcing any spotty areas in large areas of copper.

### Double-Sided PC Boards

All of the examples used to describe the above techniques were single-sided PC boards, with traces on one side of the board and either a bare board or a ground plane on the other side. PC boards can also have patterns etched onto both sides, or even have multiple layers. Most home-construction projects use single-sided boards, although some kit builders supply double-sided boards. Multilayer boards are rare in ham construction. One method for making double-sided boards is described in the sidebar, "Double-Sided PC Boards—by Hand."

### Tin Plating

Most commercial PC boards are tin plated, to make them easier to solder.

**Fig 25.25** — This home-built drill fence makes it easy to drill PC-board holes in straight rows.

**Fig 25.26** — Utility PC boards like these are available from many suppliers.

Commercial tin-plating techniques require electroplating equipment not readily available to the home constructor. Immersion tin plating solutions can deposit a thin layer of tin onto a copper PC board. Using them is easy; put some of the solution into a plastic container and immerse the board in the solution for a few minutes. The chemical action of the tin-plating solution replaces some of the copper on the board with tin. The result looks nearly as good as a commercially made board. Agitate the board or solution from time to time. When the tinning is complete, take the board out of the solution and rinse it for five minutes under running water. If you don't remove all of the residue, solder may not adhere well to the surface. Kepro sells immersion tin plating solution.

### Drilling a PC Board

After you make a PC board using one of the above techniques, you need to drill holes in the board for the components. Use a drill press, or at least improvise one. Boards can be drilled entirely "free hand"

with a hand-held drill but the potential for error is great. A drill press or a small Moto-Tool in an accessory drill press makes the job a lot easier. A single-sided board should be drilled after it is etched; the easiest way to do a double-sided board is to do it before the resist is applied.

To drill in straight lines, build a small movable guide for the drill press so you can slide one edge of the board against it and line up all of the holes on one grid line at a time. See **Fig 25.25**. This is similar to the "rip fence" set up by most woodworkers to cut accurately and repeatably with a table saw.

The drill-bit sizes available in hardware stores are too big for PC boards. You can use high-speed steel bits, but glass epoxy stock tends to dull these after a few hundred holes. (When your drill bit becomes worn, it makes a little "hill" around each drilled hole, as the worn bit pushes and pulls the copper rather than drilling it.) A PC-board drill bit, available from many electronic suppliers, will last for thousands of holes! If you are doing a lot of boards, it is clearly worth the investment.

Small drill bits are usually ordered by number. Here are some useful numbers and their sizes:

Number	Diameter
68	0.0310"
65	0.0350"
62	0.0380"
60	0.0400"

Use high RPM and light pressure to make good holes. Count the holes on both the board and your layout drawing to ensure that none are missed. Use a larger-size drill bit, lightly spun between your fingers, to remove any burrs. Don't use too much pressure; remove only the burr.

### "Ready-Made" PC Boards

#### Utility PC Boards

"Utility" PC boards are an alternative to custom-designed etched PC boards. They offer the flexibility of perforated board construction and the mechanical and electrical advantages of etched circuit connection pads. Utility PC boards can be used to build anything from simple passive filter circuits to computers.

Circuits can be built on boards on which the copper cladding has been divided into connection pads. Power supply voltages can be distributed on bus strips. Boards like those shown in **Fig 25.26** are commercially available.

An audio amplifier constructed on a utility PC board is shown in **Fig 25.27**. Component leads are inserted into the board and soldered to the etched pads. Wire jumpers connect the pads together to

(A)

(B)

**Fig 25.27** — The audio amplifier built on a multipurpose PC breadboard. Top view at A; bottom view at B.

complete the circuit.

Utility boards with one or more etched plugs for use in computer-bus, interface and general purpose applications are widely available. Connectors, mounting hardware and other accessories are also available. Check with your parts supplier for details.

### PC-Board Assembly Techniques

Once you have etched and drilled a PC board you are ready to use it in a project. Several tools come in handy: needle-nose pliers, diagonal cutters, pocket knife, wire strippers, clip leads and soldering iron.

### Cleanliness

Make sure your PC board and component leads are clean. Clean the entire PC board before assembly; clean each component before you install it. Corrosion looks dark instead of bright and shiny. Don't use sandpaper to clean your board. Use a piece of fine steel wool or a Scotchbrite cleaning pad to clean component leads or PC board before you solder them together.

### Installing Components

In a construction project that uses a PC board, most of the components are installed on the board. Installing components is easy — stick the components in the right board holes, solder the leads, and cut off the extra lead length. Most construction projects have a parts-placement diagram that shows you where each component is installed.

Getting the components in the right holes is called "stuffing" the circuit board. Inserting and soldering one component at a time takes too long. Some people like to put the components in all at once, and then turn the board over and solder all the leads. If you bend the leads a bit (about 20°) from the bottom side after you push them through the board, the components are not likely to fall out when you turn the board over.

Start with the shortest components — horizontally mounted diodes and resistors. Larger components sometimes cover smaller components, so these smaller parts must be installed first. Use adhesive tape to temporarily hold difficult components in place while you solder.

### PC-Board Soldering

To solder components to a PC board, bend the leads at a slight angle; apply the soldering iron to one side of the lead, and flow the solder in from the other side of the lead. See Fig 25.28. Too little heat causes a bad or "cold" solder joint; too much heat can damage the PC board. Prac-

tice a bit on some spare copper stock before you tackle your first PC board project. After the connection is soldered properly, clip the lead flush with the solder.

### Special Concerns

Make sure you have the components in the right holes before you solder them. Components that have polarity, such as diodes, ICs and some capacitors must be oriented as shown on the parts-placement diagram.

### FROM SCHEMATIC TO WORKING CIRCUIT

Some people don't know how to turn a schematic into a working circuit. One thing is usually true — you can't build it the way it looks on the schematic. Many design and layout considerations that apply in the real world of practical electronics don't appear on a schematic.

### PC Boards — Always the Best Choice?

PC boards are everywhere — in all kinds of consumer electronics, in most of your Amateur Radio equipment. They are also used in most kits and construction projects. A newcomer to electronics might think that there is some unwritten law against building equipment in any other way!

The misconception that everything needs to be built on a printed-circuit board is often a stumbling block to easy project construction. In fact, a PC board is probably the worst choice for a one-time project. In actuality, a moderately complex project (like a QRP transmitter) can be built in much less time using other techniques. The additional design, layout and manufacturing is usually much more work than it would take to build the project by hand.

So why does everyone use PC boards? The most important reason is that they are reproducible. They allow many units to be mass-produced with exactly the same layout, reducing the time and work of conventional wiring and minimizing the possibilities of wiring errors. If you can buy a ready-made PC board or kit for your project, it can save a lot of construction time.

Using a PC board usually makes project construction easier by minimizing the risk of wiring errors or other construction blunders. Inexperienced constructors usually feel more confident when construction has been simplified to the assembly of components onto a PC board. One of the best ways to get started with home construction (to some the best part of Amateur Radio) is to start by assembling a few kits using PC boards. The ARRL Technical

Information Service (TIS) has prepared a list of kit manufacturers. If you would like one, send an SASE, with a request for the "Kits" TIS information package, to the ARRL Technical Department Secretary.

### One-Time Projects

Kits are fun; but another facet of electronics construction is building and developing your own circuits, starting from circuit diagrams. For one-time construction, PC boards are really not necessary. It takes time to lay out, drill and etch a PC board. Alterations are difficult to make if you change your ideas or make a mistake. Most important, PC boards aren't always the best technique for building RF circuits.

### Layout

A circuit diagram is a poor guide toward a proper layout. Circuit diagrams are drawn to look attractive on paper. They follow drafting conventions that have very little to do with the way the circuit works. On a schematic, ground and supply voltage symbols are scattered all over the place. The first rule of RF layout is — *do not wire RF circuits as they are drawn!* How a circuit works in practice depends on the layout. Poor layout can ruin the performance of even a well-designed circuit.

### How to Design a Good Circuit Layout

The easiest way to explain good layout practices is to take you through an example. Fig 25.29 is the circuit diagram of a two-stage receiver IF amplifier using dual-gate MOSFETs. It is only a design example, so the values are only typical. To analyze which things are important to the layout of this circuit, ask these questions:

- Which are the RF components, and which are only involved with LF or dc?

Fig 25.28 — This is how to solder a component to a PC board. Make sure that the component is flush with the board on the other side.

- Which components are in the main RF signal path?
- Which components are in the ground return paths?

Use the answers to these questions to plan the layout. The RF components that are in the main RF signal path are usually the most critical. The AF or dc components can usually be placed anywhere. The components in the ground return path should be positioned so they are easily connected to the circuit ground. Answer the questions, apply the answers to the layout, then follow these guidelines:

- Avoid laying out circuits so their inputs and outputs are close together. If a stage's output is too near a previous stage's input, the output signal can feed-back into the input and cause problems.
- Keep component leads as short as practical. This doesn't necessarily mean as short as possible — just consider lead length as part of your design.
- Remember that metal transistor cases conduct, and that a transistor's metal case is usually connected to one of its leads. Prevent cases from touching ground or other components, unless called for in the design.

In our design example, the RF components are shown in heavy lines, though not

all of these components are in the main RF signal path. The RF signal path consists of T1/C1, Q1, T2/C4, C7, Q2, T3/C11. These need to be positioned in almost a straight line, to avoid feedback from output to input. They form the backbone of the layout, as shown in Fig 25.30A.

The question about ground paths requires some further thought — what is really meant by “ground” and “ground-return paths”? Some points in the circuit need to be kept at RF ground potential. The best RF ground potential on a PC board is a copper ground plane covering one entire side. Points in the circuit which cannot be connected directly to ground for dc reasons must be bypassed (“decoupled”) to ground by capacitors that provide ground-return paths for RF.

In Fig 25.30, the components in the ground-return paths are the RF bypass capacitors C2, C3, C5, C8, C9 and C12. R4 is primarily a dc biasing component, but it is also a dc return for RF so its location is important.

The values of RF bypass capacitors are chosen to have a low reactance at the frequency in use; typical values would be 0.1  $\mu\text{F}$  at LF, 0.01  $\mu\text{F}$  at HF, and 0.001  $\mu\text{F}$  or less at VHF. Not all capacitors are suitable for RF decoupling; the most common are disc ceramic capacitors. RF decoupling capacitors should always have

short leads.

Almost every RF circuit has an input, an output and a common ground connection. Many circuits also have additional ground connections, both at the input side and at the output side. Maintain a low-impedance path between input and output ground connections. The input ground connections for Q1 are the grounded ends of C1 and the two windings of T1. (The two ends of an IF transformer winding are generally not interchangeable; one is designated as the “hot” end, and the other must be connected or bypassed to RF ground.) The capacitor that resonates with the adjustable coil is often mounted inside the can of the IF transformer, leaving only two component leads to be grounded as shown in Fig 25.30B.

The RF ground for Q1 is its source connection via C3. Since Q1 is in a plastic package that can be mounted in any orientation, you can make the common ground either above or below the signal path in Fig 25.30B. Although the circuit diagram shows the source at the bottom, the practical circuit works much better with the source at the top, because of the connections to T2.

It's a good idea to locate the hot end of the main winding close to the drain lead of the transistor package, so the other end is toward the top of Fig 25.30B. If the source

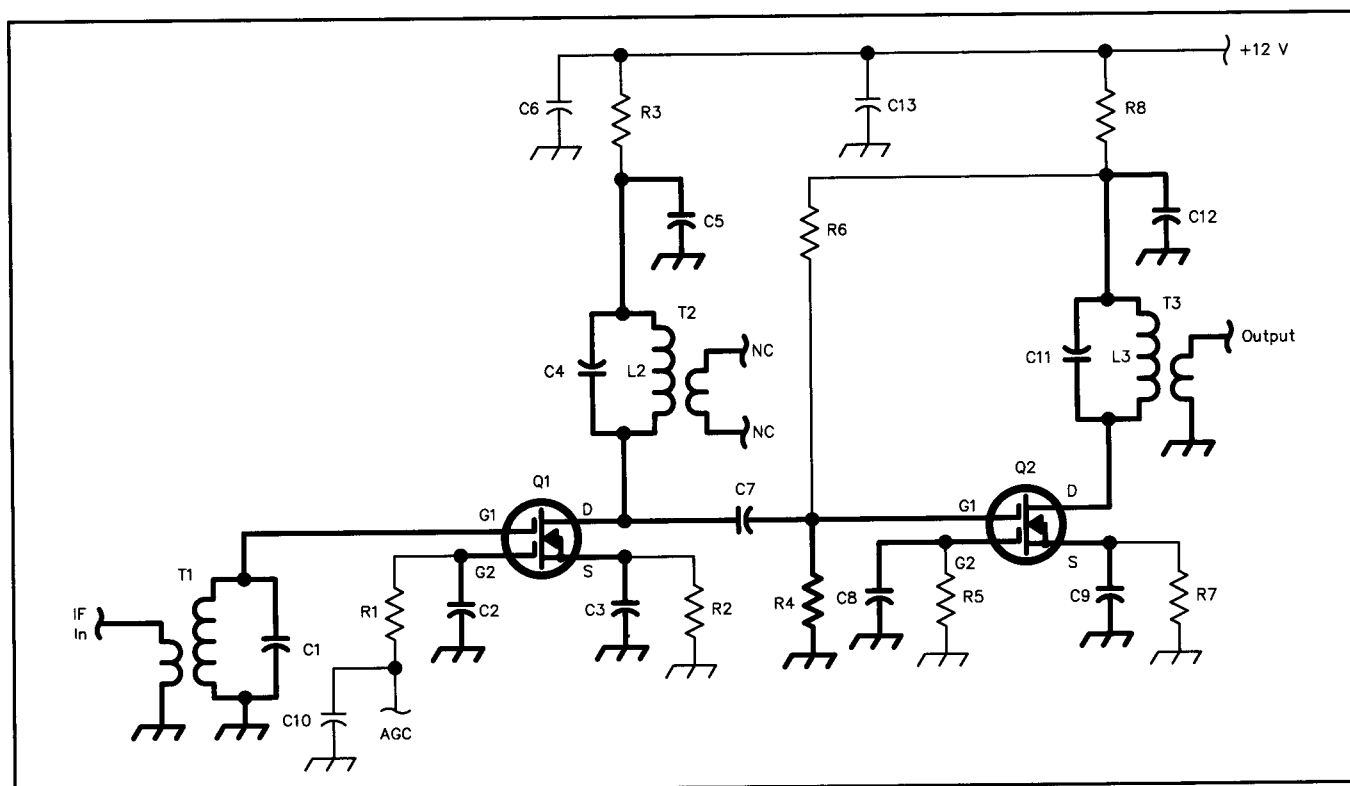

Fig 25.29 — The IF amplifier used in the design example. C1, C4 and C11 are not specified because they are internal to the IF transformers.

**Fig 25.31** — Two capacitors in parallel afford better bypassing across a wide frequency range.

**Fig 25.32** — A solder bridge has formed a short circuit between PC board traces.

for each stage, and for the whole unit. If possible, lay out all stages in a straight line. If an RF signal path doubles back or recrosses itself it usually results in instability.

- Keep the stages at different frequencies well-separated to minimize interstage coupling and spurious signals.
- Use interstage shields where necessary,

but don't rely on them to cure a bad layout.

- Make all connections to the ground plane short and direct. Locate the common ground for each stage between the input and the output ground. Single-point grounding may work for a single stage, but it is rarely effective in a complex RF system.
- Locate frequency-determining components away from heat sources and mount them so as to maximize mechanical strength.
- Avoid unwanted coupling between tuned circuits. Use shielded inductors or toroids rather than open coils. Keep the RF high-voltage points close to the ground plane. Orient air-wound coils at right angles to minimize mutual coupling.
- Use lots of extra RF bypassing, especially on dc supply lines.
- Try to keep RF and dc wiring on opposite sides of the board, so the dc wiring is well away from RF fields.
- Compact designs are convenient, but don't overdo it! If the guidelines cited above mean that a unit needs to be bigger, make it bigger.

## Combination Techniques

You can use a mixture of construction techniques on the same board and in most cases you probably should. Even though you choose one style for most of the wiring, there will probably be places where other techniques would be better. If so, do whatever is best for that part of the circuit. The resulting hybrid may not be pretty (these techniques aren't called "ugly construction" for nothing), but it will work!

Mount dual-in-line package (DIP) ICs in an array of drilled holes, then connect them using wired traces as described earlier. It is okay to mount some of the components using a ground-plane method, push pins or even wire wrap. On any one board, you may use a combination of these techniques, drilling holes for some ICs, or gluing others upside down, then surface mounting some of the pins, and other techniques to connect the rest. These combination techniques are often found in a project that combines audio, RF and digital circuitry.

## A Final Check

No matter what construction technique is chosen, do a final check before applying power to the circuit! Things do go wrong, and a careful inspection minimizes the risk of a project beginning and ending its life as a puff of smoke! Check wiring carefully. Make a photocopy of the schematic and mark each lead on the schematic with a red X when you've verified that it's connected to the right spot in the circuit.

Inspect solder connections. A bad solder joint is much easier to find before the PC board is mounted to a chassis. Look for any damage caused to the PC board by soldering. Look for solder "bridges" between adjacent circuit-board traces. Solder bridges (Fig 25.32), occur when solder accidentally connects two or more conductors that are supposed to be isolated. It is often difficult to distinguish a solder bridge from a conductive trace on a tin-plated board. If you find a bridge, remelt it and the adjacent trace or traces to allow the solder's surface tension to absorb it. Double check that each component is installed in the proper holes on the board and that the orientation is correct. Make sure that no component leads or transistor tabs are touching other components or PC board connections. Check the circuit voltages before installing ICs in their sockets. Ensure that the ICs are oriented properly and installed in the correct sockets.

of Q1 is also toward the top of the layout, there is a common ground point for C3 (the source bypass capacitor) and the output bypass capacitor C5. Gate 2 of Q1 can safely be bypassed toward the bottom of the layout.

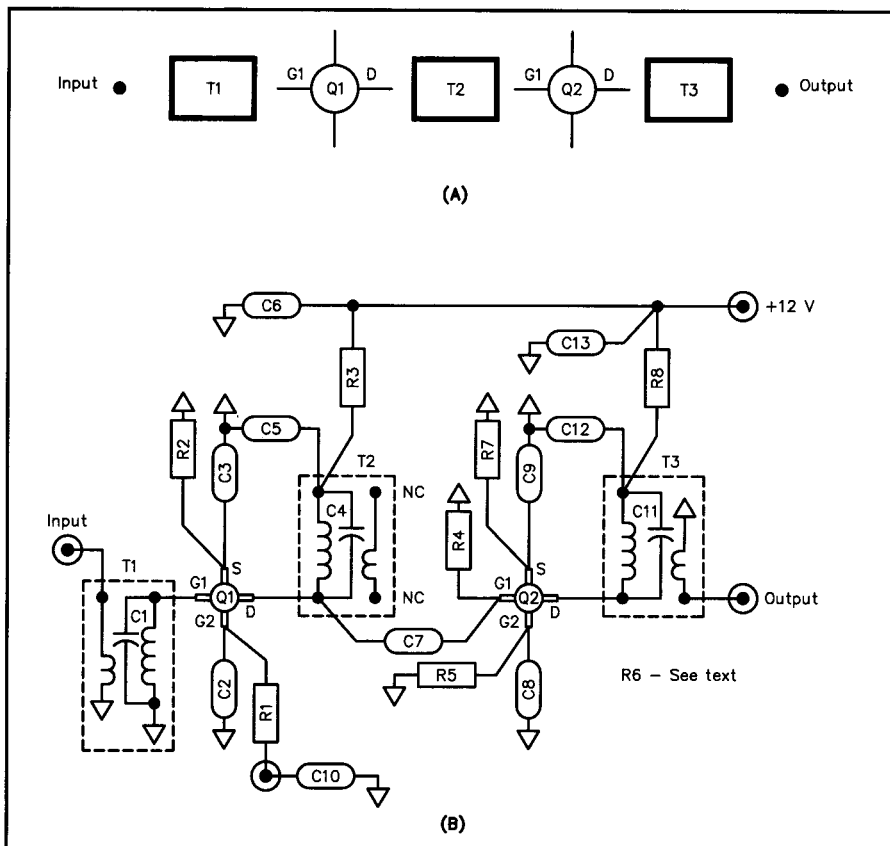

C7 couples the signal from the output of Q1 to the input of Q2. The source of Q2 should be bypassed toward the top of the layout, in exactly the same way as the source of Q1. R4 is not critical, but it should be connected on the same side as the other components. Note how the pinout of T3 has placed the output connection as far as possible from the input. With this layout for the signal path and the critical RF components, the circuit has an excellent chance of working properly.

### DC Components

The rest of the components carry dc, so their layout is much less critical. Even so, try to keep everything well separated from the main RF signal path. One good choice is to put the 12-V connections along the top of the layout, and the AGC connection at the bottom. The source bias resistors R2 and R7 can be placed alongside C3 and C9. The gate-2 bias resistors for Q2, R5 and R6 are not RF components so their locations aren't too critical. R7 has to cross the signal path in order to reach C12, however, and the best way to avoid signal pickup would be to mount R7 on the opposite side of the copper ground plane from the signal wiring. Generally speaking, 1/8-W or 1/4-W metal-film or carbon-film resistors are best for low-level RF circuits.

Actually, it is not quite accurate to say that resistors such as R3 and R8 are not "RF" components. They provide a high impedance to RF in the positive supply lead. Because of R8, for example, the RF signal in T2 is conducted to ground through C5 rather than ending up on the 12-V line, possibly causing unwanted RF feedback. Just to be sure, C6 bypasses R3 and C13 serves the same function for R8. Note that the gate-2 bias resistor R6 is connected to C12 rather than directly to the 12-V supply, to take advantage of the extra decoupling provided by R8 and C13.

If you build something, you want it to work the first time, so don't cut corners! Some commercial PC boards take liberties with layout, bypassing and decoupling. Don't assume that you can do the same. Don't try to eliminate "extra" decoupling components such as R3, C6, R8 and C13, even though they might not all be absolutely necessary. If other people's designs have left them out, put them in again. In the long run it's far easier to take a little more time and use a few extra components, to build in some insur-

**Fig 25.30 — Layout sketches.** The preliminary line-up is shown in A; the final layout in B.

ance that your circuit will work. For a one-time project, the few extra parts won't hurt your pocket too badly; they may save untold hours in debugging time.

A real capacitor does not work well over a large frequency range. A 10- $\mu$ F electrolytic capacitor cannot be used to bypass or decouple RF signals. A 0.1- $\mu$ F capacitor will not bypass UHF or microwave signals. Choose component values to fit the range. The upper frequency limit is limited by the series inductance,  $L_s$ . In fact, at frequencies higher than the frequency at which the capacitor and its series inductance form a resonant circuit, the capacitor actually functions as an inductor. This is why it is a common practice to use two capacitors in parallel for bypassing, as shown in Fig 25.31. At first glance, this might appear to be unnecessary. However, the self-resonant frequency of C1 is usually 1 MHz or less; it cannot supply any bypassing above that frequency. However, C2 is able to bypass signals up into the lower VHF range.

Let's summarize how we got from Fig 25.29 to Fig 25.30B:

- Lay out the signal path in a straight line.
- By experimenting with the placement and orientation of the components in the

RF signal path, group the RF ground connections for each stage close together, without mixing up the input and output grounds.

- Place the non-RF components well clear of the signal path, freely using decoupling components for extra measure.

### Practical Construction Hints

Now it's time to actually construct a project. The layout concepts discussed earlier can be applied to nearly any construction technique. Although you'll eventually learn from your own experience, the following guidelines give a good start:

- Divide the unit into modules built into separate shielded enclosures — RF, IF, VFO, for example. Modular construction improves RF stability, and makes the individual modules easier to build and test. It also means that you can make major changes without rebuilding the whole unit. RF signals between the modules can usually be connected using small coaxial cable.
- Use a full copper ground plane. This is your largest single assurance of RF stability and good performance.
- Keep inputs and outputs well separated

## Microwave Construction Techniques

Microwave construction is becoming more popular, but at these frequencies the size of physical component leads and PC-board traces cannot be neglected. Microwave construction techniques either minimize these stray values or make them part of the circuit design.

Microwave construction does not always require tight tolerances and precision construction. A fair amount of error can often be tolerated if you are willing to tune your circuits, as you do at MF/HF. This usually requires the use of variable components that can be expensive and tricky to adjust.

Proper design and construction techniques, using high precision, can result in a "no-tune" microwave design. To build one of these no-tune projects, all you need do is buy the parts and install them on the board. The circuit tuning has been precisely controlled by the board and component dimensions so the project should work.

One tuning technique you can use with a microwave design, if you have the suitable test equipment, is to use bits of copper foil or EMI shielding tape as "stubs" to tune circuits. Solder these small bits of conductor into place at various points in the circuit to make reactances that can actually tune a circuit. After their position has been determined as part of the design, tuning is accomplished by removing or adding small amounts of conductor, or slightly changing the placement of the tuning stub. The size of the foil needed depends on your ability to determine changes in circuit performance, as well as the frequency of operation and the circuit board parameters. A precision setup that lets you see tiny changes allows you to use very small pieces of foil to get the best tuning possible.

From a mechanical accuracy point of view, the most tolerant type of construction is waveguide construction. Tuning is usually accomplished via one or more screws threaded into the waveguide. It becomes unwieldy to use waveguide on the amateur bands below 10 GHz because the dimensions get too large.

At 24 GHz and above, even waveguide becomes small and difficult to work with. At these frequencies, most readily available coax connectors work unreliably, so these higher bands are really a challenge. Special SMA connectors are available for use at 24 GHz.

Modular construction is a useful technique for microwave circuits. Often, circuits are tested by hooking their inputs and output to known 50- $\Omega$  sources and loads. Modules are typically kept small to prevent the chassis and PC board from acting as a waveguide, providing a feedback path between the input and output of a circuit, resulting in instability.

At microwave frequencies, the mechanical aspects and physical size of circuits become very much a part of the design. A few millimeters of conductor has significant reactance at these frequencies. This even affects VHF and HF designs! The traces and conductors used in an

HF or VHF design resonate on microwave frequencies. If a high-performance FET has lots of gain in this region, a VHF preamplifier might also function as a 10-GHz oscillator if the circuit stray reactances were just right (or wrong!). You can prevent this by using shields between the input and output or by adding microwave absorptive material to the lid of the shielded module. (SHF Microwave sells absorptive materials. See the Address List in the **References** chapter.)

It is important to copy microwave circuits exactly, unless you really know what you are doing. "Improvements," such as better shielding or grounding can sometimes cause poor performance. It isn't usually attractive to substitute components, particularly with the active devices. It may look possible to substitute different grades of the same wafer, such as the ATF13135 and the AFT13335, but these are really the same transistor with different performance measurements. While two transistors may have exactly the same gain and noise figure at the desired operating frequency, often the impedances needed to maintain stability at other frequencies are different. Thus, the "substitute" may oscillate, while the proper transistor would work just fine.

You can often substitute MMICs (monolithic microwave integrated circuits) for one another because they are designed to be stable and operate with the same input and output impedances (50  $\Omega$ ).

The size of components used at microwaves can be critical—in some cases, a chip resistor 80 mils across is not a good substitute for one 60 mils across. Hopefully, the author of a construction project tells you which dimensions are critical, but you can't always count on this; the author may not know. It's not unusual for a person to spend years building just one prototype, so it's not surprising that the author might not have built a dozen different samples to try possible substitutions.

When using glass-epoxy PC board at microwave frequencies, the crucial board parameter is the thickness of the dielectric. It can vary quite a bit, in excess of 10%. This is not surprising; digital and lower-frequency analog circuits work just fine if the board is a little thinner or thicker than usual. Some of the board types used in microwave-circuit construction are a generic teflon PC board, Duroid 5870 and 5880. These boards are available from Microwave Components of Michigan. See the Address List in the **References** chapter.

Proper connectors are a necessary expense at microwaves. At 10 GHz, the use of the proper connectors is essential for repeatable performance. Do not hook up microwave circuits with coax and pigtailed. It might work but it probably can't be duplicated. SMA connectors are common because they are small and work well. SMA jacks are sometimes soldered in place, although 2-56 hardware is more common. — *Zack Lau, KH6CP, ARRL Laboratory Engineer*

## Other Construction Techniques

### Wiring

Select the wire used in connecting amateur equipment by considering: the maximum current it must carry, the voltage its insulation must withstand and its use.

To minimize EMI, the power wiring of all transmitters should use shielded wire.

Receiver and audio circuits may also require the use of shielded wire at some points for stability or the elimination of hum. Coaxial cable is recommended for all 50- $\Omega$  circuits. Use it for short runs of high-impedance audio wiring.

When choosing wire, consider how much current it will carry. The Wire Table in the **References** chapter lists common

wire sizes and current capacities. Stranded wire is usually preferred over solid wire because stranded wire better withstands the inevitable bending that is part of building and troubleshooting a circuit. Solid wire is more rigid than stranded wire; use it where mechanical rigidity is needed or desired.

Wire with typical plastic insulation is

## How to Buy Parts for Electronics Projects

The number one question received by the ARRL Technical Information Service starts out "Where can I buy..." It seems that one of the most perplexing problems faced by the would-be constructor is where to get parts. Sometimes you are lucky—the circuit author has made a kit available. But not every project has a ready-made kit. If you would like to expand your construction horizons, you can learn to be your own "purchasing manager." That means searching out parts sources and dealing with them in person.

In reality, it is not all that difficult to find most parts. Unfortunately, though, the days of the local electronic parts supplier seem to be gone. This is not surprising. Years ago an electronics supplier had to stock a relatively small number of electronic components — resistors, capacitors, tube sockets, a few relays and variable resistors. Technology has increased the number of components by a few orders of magnitude. Nowadays, the number of integrated circuits alone is enough to fill a multivolume book. No single electronics supplier could possibly stock them all. It has become a mail-order world; the electronics world is no exception.

Although it is no longer always possible to purchase all of your electronic needs from a local electronics supplier, the good news is that you don't have to! For a few dollars, mail-order companies are willing to supply whatever you need. You only need do two things to obtain nearly any electronic component — make a phone call and write a check.

Become an electronic catalog collector. The **References** chapter has a list of electronic-component suppliers. Write to these companies and request their catalogs. Electronic suppliers also advertise in magazines that cater to ham-radio and electronics enthusiasts. If you are lucky, you may have a local source of electronics parts. Look in the Yellow Pages under "Electronic Equipment Suppliers" to find the local outlets. Radio Shack is one local source found nearly everywhere. They carry an assortment of the more common electronic parts. You'll probably need to order from more than one mail-order company. (It's almost a corollary to Murphy's Law: No matter how wide a selection you find in one mail-order catalog, there's always at least one part you must buy somewhere else!)

While you're waiting for your catalogs, look at the parts list for the project you want to build. Unfortunately, you can't just photocopy the list and send it off to a mail-order company with a note that says "please send me these parts." You need to convert the part list into a part-order list that shows the order number and quantity required of each component. This may require a similar list for each parts supplier where one supplier does not have all the parts.

Check the type, tolerance, power rating and other key characteristics of the parts. Group the parts by those parameters before grouping them by value. If all of the circuit's components are already grouped by value on the

parts list, you can just count the number of each value. Each time you add parts to the order list, check them off the published parts list. Sometimes the parts list does not include common components like resistors and capacitors. If this is the case, make a copy of the schematic and check off the parts as you build your shopping list.

Although you'll probably be able to order exactly the right number of each part for a project, buy a few extras of some parts for your junk box. It's always good to have a few extra parts on hand; you may break a component lead during assembly, or damage a solid-state component with too much heat or by wiring it in backwards. If you don't have extras, you'll need to order another part. Even if you don't need the extras for this project, they may come in handy, and you'll be encouraged to build another project! Pick up an extra toroid or two as well.

Now's the time to decide whether you're going to build your project with ground-plane construction or PC board. If you need a PC-board, FAR Circuits and others have them for many ARRL book and QST projects. If you're going to use ground-plane construction, buy a good-sized piece of single-sided copper-clad board—glass-epoxy board if you can. Phenolic board is inferior because it is brittle and deteriorates rapidly with soldering heat.

Don't forget an enclosure for your project. This is often overlooked in parts lists for most projects, because different builders like different enclosures. Make sure there's room in the box for all of the components used in your project. Some people like to cram projects in the smallest possible box, but miniaturization can be extremely frustrating if you're not good at it.

There are almost always a few items you can't get from one company and most have minimum orders. You may need to distribute your order between two or more companies to meet minimum-order requirements. Some companies put out beautiful catalogs, but their minimum order is \$25 or they charge \$5 for shipping if you place a small order.

If you order enough parts, you'll soon find out which companies you like to deal with and which have slow service. It is frustrating to receive most of an order, then wait months for the parts that are on back-order. If you don't want the company to back-order your parts, write clearly on the order form, "Do not back-order parts." They will then ship the parts they have and leave you to order the rest from somewhere else.

If you are in a hurry, call the company to inquire about the availability of the parts in your order. Some companies take credit-card orders over the telephone. Some companies hold orders a few weeks to allow personal checks to clear.

If you are familiar with the catalogs and policies of electronic-component suppliers, you will find that getting parts is not difficult. Concentrate on the fun part — building the circuit and getting it working. —*Bruce Hale, KB1MW*

good for voltages up to about 500 V. Use Teflon-insulated or other high-voltage wire for higher voltages. Teflon insulation does not melt when a soldering iron is applied. This makes it particularly helpful in tight places or large wiring harnesses. Although Teflon-insulated

wire is more expensive, it is often available from industrial surplus houses. Inexpensive wire strippers make the removal of insulation from hookup wire an easy job. Solid wire is often used to wire HF circuits. Bare soft-drawn tinned wire, #22 to #12 (depending on me-

chanical requirements) is suitable. Avoid kinks by stretching a piece 10 or 15 ft long and then cutting it into short, convenient lengths. Run RF wiring directly from point to point with a minimum of sharp bends and keep the wire well-spaced from the chassis or other

grounded metal surfaces. Where the wiring must pass through the chassis or a partition, cut a clearance hole and line it with a rubber grommet. If insulation is necessary, slip spaghetti insulation or heat-shrink tubing over the wire. For power-supply leads, bring the wire through the chassis via a feedthrough capacitor.

In transmitters where the peak voltage does not exceed 500 V, shielded wire is satisfactory for power circuits. Shielded wire is not readily available for higher voltages — use point-to-point wiring instead. In the case of filament circuits carrying heavy current, it is necessary to use #10 or #12 bare or enameled wire. Slip the bare wire through spaghetti then cover it with copper braid pulled tightly over the spaghetti. Slide the shielding back over the insulation and flow solder into the end of the braid; the braid will stay in place, making it unnecessary to cut it back or secure it in place. Clean the braid first so solder will take with a minimum of heat.

For receivers, RF wiring follows the methods described above. At RF, most of the current flows on the surface of the wire (a phenomenon called “skin effect”). Hollow tubing is just as good a conductor at RF as solid wire.

### High-Voltage Techniques

High-voltage wiring requires special care. You need to use wire rated for the voltage it is carrying. Most standard hookup wire is inadequate. High-voltage wire is usually insulated with Teflon or special multilayer plastic. Some coaxial cable is rated at up to 3700 V.

Air is a great insulator, but high voltage can break down its resistance and form an arc. You need to leave ample room between any circuit carrying voltage and any nearby conductors. At dc, leave a gap of at least 0.1 inch per kilovolt. The actual breakdown voltage of air varies with the frequency of the signal, humidity and the shape of the conductors.

High voltage is also prone to corona discharge, a bleeding off of charge, primarily from sharp edges. For this reason, all connections need to be soldered, leaving only rounded surfaces on the soldered connection. It takes a little practice to get a “ball” of solder on each joint, but for voltages above 5 kV it is important.

Be careful working near high-voltage circuits! Most high-voltage power supplies can deliver a lethal shock.

### Cable Lacing and Routing

Where power or control leads run together for more than a few inches, they present a better appearance when bound

together in a single cable. Both plastic and waxed-linen lacing cords are available. You can also use a variety of plastic devices to bundle wires into cables and to clamp or secure them in place. Fig 25.33 shows some of the products and techniques that you might use. Check with your local electronic parts supplier for items that are in stock.

To give a commercial look to the wiring of any unit, route any dc leads and shielded signal leads along the edge of the chassis. If this isn't possible, the cabled leads should then run parallel to an edge of the chassis. Further, the generous use of the tie points mounted parallel to an edge of the chassis, for the support of one or both ends of a resistor or fixed capacitor, adds to the appearance of the finished unit. In a similar manner, arrange the small components so that they are parallel to the panel or sides of the chassis.

### Tie Points

When power leads have several branches in the chassis, it is convenient to use fiber-insulated multiple tie points as anchors for junction points. Strips of this kind are also useful as insulated supports for resistors, RF chokes and capacitors. Hold exposed points of high-voltage wiring to a minimum; otherwise, make them inaccessible to accidental contact.

### Winding Coils

Winding coils seems so simple, yet many new constructors run into difficulty. Understanding the techniques prevents some of the frustration or construction errors associated with coil winding.

Close-wound coils are readily wound on the specified form by anchoring one end of the length of wire (in a vise or to a doorknob) and the other end to the coil form. Straighten any kinks in the wire and then pull to keep the wire under slight tension. Wind the coil to the required number of turns while walking toward the anchor, always maintaining a slight tension on the wire.

To space-wind the coil, wind the coil simultaneously with a suitable spacing medium (heavy thread, string or wire) in the manner described above. When the winding is complete, secure the end of the coil to the coil-form terminal and then carefully unwind the spacing material. If the coil is wound under suitable tension, the spacing material can be easily removed without disturbing the winding. Finish space-wound coils by judicious applications of Duco cement to hold the turns in place.

The “cold” end of a coil is the end at (or close to) chassis or ground potential. Wind coupling links on the cold end of a coil to minimize capacitive coupling.

### Winding Toroidal Inductors

Toroidal inductors and transformers are specified for many projects in this *Handbook*. The advantages of these cores include compactness and a self-shielding property. Figs 25.34 and 25.35 illustrate the proper way to wind and count turns on a toroidal core.

Fig 25.33 — Adhesive-backed blocks and plastic wraps used to make wiring cables.

Fig 25.34—The maximum-Q method for winding a single-layer toroid is shown at A. A 30° gap is best. Methods at B and C have greater distributed capacitance. D shows how to place a tap on a toroid coil winding.

Fig 25.35—A shows a toroid core with two turns of wire (see text). Large black dots, like those at T1 in B, indicate winding polarity (see text).

**Fig 25.36 — Schematic and pictorial presentation of a bifilar-wound toroidal transformer.**

When you wind a toroid inductor, count each pass of the wire through the toroid center as a turn. You can count the number of turns by counting the number of times the wire passes through the center of the core. See Fig 25.35A.

### Multiwire Windings

A bifilar winding is one that has two identical lengths of wire, which when placed on the core result in the same number of turns for each wire. The two wires are wound on the core side by side at the same time, just as if a single winding were being applied. An easier and more popular method is to twist the two wires (8 to 15 turns per inch is adequate), then wind the twisted pair on the core. The wires can be twisted handily by placing one end of each in a bench vise. Tighten the remaining ends in the chuck of a small hand drill and turn the drill to twist the pair.

A trifilar winding has three wires, and a quadrifilar winding has four. The procedure for preparation and winding is otherwise the same as for a bifilar winding. Fig 25.36 shows a bifilar toroid in schematic and pictorial form. The wires have been twisted together prior to placing them on the core. It is helpful, though by no means essential, to use wires of different color when multifilar-winding a core. It is more difficult to identify multiple windings on a core after it has been wound. Various colors of enamel insulation are available, but it is not easy for amateurs to find this wire locally or in small-quantity lots. This problem can be solved by taking lengths of wire (enameled magnet wire), cleaning the ends to remove dirt and grease, then spray painting them. Ordinary aerosol-can spray enamel works fine. Spray lacquer is not as satisfactory because it is brittle when dry and tends to flake off the wire.

The winding sense of a multifilar toroidal transformer is important in most circuits. Fig 25.35B illustrates this principle. The black dots (called phasing dots) at the top of the T1 windings indicate polarity. That is, points a and c are both start or

finish ends of their respective windings. In this example, points b and d are of opposite phase (180° phase difference) to provide push-pull voltage feed to Q1 and Q2.

After you wind a coil, scrape the insulation off the wire before you solder it into the circuit.

## MECHANICAL FABRICATION

Electronic construction has many mechanical aspects. Cutting, bending and drilling are part of most electronic-construction projects.

### Buy or Build a Chassis?

Most projects end up in some sort of an enclosure, and most hams choose to purchase a ready-made chassis for small projects, but some projects require a custom enclosure. Even a ready-made chassis may require a fabricated sheet-metal shield or bracket, so it's good to learn something about sheet-metal and metal-fabrication techniques.

Most often, you can buy a suitable enclosure. These are sold by Radio Shack and most electronics distributors. See the list in the **References** chapter.

Select an enclosure that has plenty of room. A removable cover or front panel can make any future troubleshooting or modifications easy. A project enclosure should be strong enough to hold all of the components without bending or sagging; it should also be strong enough to stand up to expected use and abuse.

### Cutting and Bending Sheet Metal

Enclosures, mounting brackets and shields are usually made of sheet metal. Most sheet metal is sold in large sheets, 4x8 ft or larger. It must be cut to the size needed.

Most sheet metal is thin enough to cut with metal shears or a hacksaw. A jigsaw or bandsaw makes the task easier. If you use any kind of saw, select a blade that has teeth fine enough so that at least two teeth are in contact with the metal at all times.

If a metal sheet is too large to cut conveniently with a hacksaw, it can be scored and broken. Make scratches as deep as possible along the line of the cut on both sides of the sheet. Then, clamp it in a vise and work it back and forth until the sheet breaks at the line. Do not bend it too far before the break begins to weaken, or the edge of the sheet might bend. A pair of flat bars, slightly longer than the sheet being bent, make it easier to hold a sheet firmly in a vise. Use "C" clamps to keep the bars from spreading at the ends.

Smooth rough edges with a file or by sanding with a large piece of emery cloth

or sandpaper wrapped around a flat block.

### Finishing Aluminum

Give aluminum chassis, panels and parts a sheen finish by treating them in a caustic bath. Use a plastic container to hold the solution. Ordinary household lye can be dissolved in water to make a bath solution. Follow the directions on the container. A strong solution will do the job more rapidly.

Stir the solution with a stick of wood until the lye crystals are completely dissolved. If the lye solution gets on your skin, wash with plenty of water. If you get any in your eyes, immediately rinse with plenty of clean, room-temperature water and seek medical help. It can also damage your clothing, so wear something old. Prepare sufficient solution to cover the piece completely. When the aluminum is immersed, a very pronounced bubbling takes place. Provide ventilation to disperse the escaping gas. A half hour to two hours in the bath is sufficient, depending on the strength of the solution and the desired surface characteristics.

### Chassis Working

With a few essential tools and proper procedure, building radio gear on a metal chassis is a relatively simple matter. Aluminum is better than steel, not only because it is a superior shielding material, but also because it is much easier to work and provides good chassis contact when used with secure fasteners.

Spend sufficient time planning a project to save trouble and energy later. The actual construction is much simpler when all details are worked out beforehand. Here we discuss a large chassis-and-cabinet project, such as a high-power amplifier. The techniques are applicable to small projects as well.

Cover the top of the chassis with a piece of wrapping paper or graph paper. Fold the edges down over the sides of the chassis and fasten them with adhesive tape. Place the front panel against the chassis front and draw a line there to indicate the chassis top edge.

Assemble the parts to be mounted on the chassis top and move them about to find a satisfactory arrangement. Consider that some will be mounted underneath the chassis and ensure that the two groups of components won't interfere with each other.

Place controls with shafts that extend through the cabinet first, and arrange them so that the knobs will form the desired pattern on the panel. Position the shafts perpendicular to the front chassis edge. Locate any partition shields and panel brackets next,

then sockets and any other parts. Mark the mounting-hole centers of each part accurately on the paper. Watch out for capacitors with off-center shafts that do not line up with the mounting holes. Do not forget to mark the centers of socket holes and holes for wiring leads. Make the large center hole for a socket *before* the small mounting holes. Then use the socket itself as a template to mark the centers of the mounting holes. With all chassis holes marked, center-punch and drill each hole.

Next, mount on the chassis the capacitors and any other parts with shafts extending to the panel. Fasten the front panel to the chassis temporarily. Use a machinist's square to extend the line (vertical axis) of any control shaft to the chassis front and mark the location on the front panel at the chassis line. If the layout is complex, label each mark with an identifier. Also mark the back of the front panel with the locations of any holes in the chassis front that must go through the front panel. Remove the front panel.

### PC-Board Materials

Much tedious sheet-metal work can be eliminated by fabricating chassis and enclosures from copper-clad printed-circuit board material. While it is manufactured in large sheets for industrial use, some hobby electronics stores and surplus outlets market usable scraps at reasonable prices. PC-board stock cuts easily with a small hacksaw. The nonmetallic base material isn't malleable, so it can't be bent. Corners are easily formed by holding two pieces at right angles and soldering the seam. This technique makes excellent RF-tight enclosures. If mechanical rigidity is required of a large copper-clad surface, solder stiffening ribs at right angles to the sheet.

**Fig 25.37** shows the use of PC-board stock to make a project enclosure. This enclosure was made by cutting the pieces to size, then soldering them together. Start by laying the bottom piece on a workbench, then placing one of the sides in place at right angles. Tack-solder the second piece in two or three places, then start at one end and run a bead of solder down the entire seam. Use plenty of solder and plenty of heat. Continue with the rest of the pieces until all but the top cover is in place.

In most cases, it is better to drill all needed holes in advance. It can sometimes be difficult to drill holes after the enclosure is soldered together.

You can use this technique to build enclosures, subassemblies or shields. This technique is easy with practice; hone your skills on a few scrap pieces of PC-board stock.

### Drilling Techniques

Before drilling holes in metal with a hand

drill, indent the hole centers with a center punch. This prevents the drill bit from "walking" away from the center when starting the hole. Predrill holes greater than 1/2-inch in diameter with a smaller bit that is large enough to contain the flat spot at the large bit's tip. When the metal being drilled is thinner than the depth of the drill-bit tip, back up the metal with a wood block to smooth the drilling process.

The chuck on the common hand drill is limited to 3/8-inch bits. Some bits are much larger, with a 3/8-inch shank. If necessary, enlarge holes with a reamer or round file. For very large or odd-shaped holes, drill a series of closely spaced small holes just inside of the desired opening. Cut the metal remaining between the holes with a cold chisel and file or grind the hole to its finished shape. A nibbling tool also works well for such holes.

Use socket-hole punches to make socket holes and other large holes in an aluminum chassis. Drill a guide hole for the punch center bolt, assemble the punch with the bolt through the guide hole and tighten the bolt to cut the desired hole. Oil the threads of the bolt occasionally.

Cut large circular holes in steel panels or chassis with an adjustable circle cutter ("flycutter"). Occasionally apply machine oil to the cutting groove to speed the job. Test the cutter's diameter setting by cutting a block of wood or scrap material first.

Remove burrs or rough edges that result from drilling or cutting with a burr-remover, round or half-round file, a sharp knife or chisel. Keep an old chisel sharpened and available for this purpose.

### Rectangular Holes

Square or rectangular holes can be cut with a nibbling tool or a row of small holes as previously described. Large openings can be cut easily using socket-hole punches.

### Construction Notes

If a control shaft must be extended or insulated, a flexible shaft coupling with adequate insulation should be used. Satisfactory support for the shaft extension, as well as electrical contact for safety, can be provided by means of a metal panel bushing made for the purpose. These can be obtained singly for use with existing shafts, or they can be bought with a captive extension shaft included. In either case the panel bushing gives a solid feel to the control. The use of fiber washers between ceramic insulation and metal brackets, screws or nuts will prevent the ceramic parts from breaking.

### Painting

Painting is an art, but, like most arts, successful techniques are based on skills that

**Fig 25.37 — A chassis made entirely from PC-board stock.**

can be learned. The surfaces to be painted must be clean to ensure that the paint will adhere properly. In most cases, you can wash the item to be painted with soap, water and a mild scrub brush, then rinse thoroughly. When it is dry, it is ready for painting. Avoid touching it with your bare hands after it has been cleaned. Your skin oils will interfere with paint adhesion. Wear rubber or clean cotton gloves.

Sheet metal can be prepared for painting by abrading the surface with medium-grade sandpaper, making certain the strokes are applied in the same direction (not circular or random). This process will create tiny grooves on the otherwise smooth surface. As a result, paint or lacquer will adhere well. On aluminum, one or two coats of zinc chromate primer applied before the finish paint will ensure good adhesion.

Keep work areas clean and the air free of dust. Any loose dirt or dust particles will probably find their way onto a freshly painted project. Even water-based paints produce some fumes, so properly ventilate work areas.

Select a paint suitable to the task. Some paints are best for metal, others for wood and so on. Some dry quickly, with no fumes; others dry slowly and need to be thoroughly ventilated. You may want to select a rust-preventative paint for metal surfaces that might be subjected to high moisture or salts.

Most metal surfaces are painted with some sort of spray, either from a spray gun or from spray cans of paint. Either way, follow the manufacturer's instructions for a high-quality job.

### Summary

If you're like most amateurs, once you've got the building bug, you won't let your soldering iron stay cold for long. Starting is the hardest part. Now, the next time you think about adding another project to your station, you'll know where to start.

# Test Procedures and Projects

## 26

**T**his chapter, written by ARRL Technical Advisor Doug Millar, K6JEY, covers the test equipment and measurement techniques common to Amateur Radio. With the increasing complexity of amateur equipment and the availability of sophisticated test equipment, measurement and test procedures have also become more complex. There was a time when a simple bakelite cased volt-ohm meter (VOM) could solve most problems. With the advent of modern circuits that use advanced digital techniques, precise readouts and higher frequencies, test requirements and equipment have changed. In addition to the test procedures in this chapter, other test procedures appear in Chapters 14 and 15.

### TEST AND MEASUREMENT BASICS

The process of testing requires a knowledge of what must be measured and what accuracy is required. If battery voltage is measured and the meter reads 1.52 V, what does this number mean? Does the meter always read accurately or do its readings change over time? What influences a meter reading? What accuracy do we need for a meaningful test of the battery voltage?

#### A Short History of Standards and Traceability

Since early times, people who measured things have worked to establish a system of consistency between measurements and measurers. Such consistency ensures that a measurement taken by one person could be duplicated by others — that measurements are reproducible. This allows discussion where everyone can be assured that their measurements of the same quan-

tity would have the same result. In most cases, and until recently, consistent measurements involved an artifact: a physical object. If a merchant or scientist wanted to know what his pound weighed, he sent it to a laboratory where it was compared to the official pound. This system worked well for a long time, until the handling of the standard pound removed enough molecules so that its weight changed and measurements that compared in the past no longer did so.

Of course, many such measurements depended on an accurate value for the force of gravity. This grew more difficult with time because the outside environment — such things as a truck going by in the street — could throw the whole procedure off. As a result, scientists switched to physical constants for the determination of values. As an example, a meter was defined as a stated fraction of the circumference of the Earth over the poles.

Generally, each country has an office that is in charge of maintaining the integrity of the standards of measurement and is responsible for helping to get those standards into the field. In the United States that office is the National Institute of Standards and Testing (NIST), formerly the National Bureau of Standards. The NIST decides what the volt and other basic units should be and coordinates those units with other countries. For a modest fee, NIST will compare its volt against a submitted sample and report the accuracy of the sample. In fact, special batteries arrive there each day to be certified and returned so laboratories and industry can verify that their test equipment really does mean 1.527 V when it says so.

### Basic Units: Frequency and Time

Frequency and time are the most basic units for many purposes and the ones known to the best accuracy. The formula for converting one to the other is to divide the known value into 1. Thus the time to complete a single cycle at 1 MHz = 0.000001 s.

The history of the accuracy of time keeping, of course, begins with the clock. Wooden clocks, water clocks and mechanical clocks were ancestors to our current standard: the electronic clock based on frequency. In the 1920s, quartz crystal controlled clocks were developed in the laboratory and used as a standard. With the advent of radio communication time intervals could be transmitted by radio, and a very fundamental standard of time and frequency could be used locally with little effort. Today transmitters in several countries broadcast time signals on standard calibrated frequencies. **Table 26.1** contains the locations and frequencies of some of these stations.

In the 1960s, Hewlett-Packard began selling self-contained time and frequency standards called cesium clocks. In a cesium clock a crystal frequency is generated and multiplied to microwave frequencies. That energy is passed through a chamber filled with cesium gas. The gas acts as a very narrow band-pass filter. The output signal is detected and the crystal oscillator frequency is adjusted automatically so that a maximum of energy is detected. The output of the crystal is thus linked to the stability of the cesium gas and is usually accurate to several parts in  $10^{-12}$ . This is much superior to a crystal oscillator alone; but at close to \$40,000

**Table 26.1****Standard Frequency Stations**

<i>Call Sign</i>	<i>Location</i>	<i>Frequency (MHz)</i>
BSF	Taiwan	5
CHU	Ottawa, Canada	3.330, 7.335, 14.670
FFH	France	2.500

ZUO	South Africa	2.5, 5, 10

each, cesium frequency standards are a bit extravagant for amateur use.

A rubidium frequency standard is an alternative to the cesium clock. They are not quite as accurate as the cesium, but they are much less expensive, relatively quick to warm up and can be quite small. Older models occasionally appear surplus. As with any precision instrument, it should be checked over and calibrated before use.

Most hams do not have access to cesium or rubidium standards—or need them. Instead we use crystal oscillators. Crystal oscillators provide three levels of stability. The least accurate is a single crystal mounted on a circuit board. The crystal frequency is affected by the temperature environment of the equipment, to the extent of a few parts per million (ppm) per degree Celsius. For example, the frequency of a 10-MHz crystal with temperature stability rated at 3 ppm might vary 60 Hz when temperature of the crystal changes by 2°C. If the crystal oscillator is followed by a frequency multiplier, any variation in the crystal frequency is also multiplied. Even so, the accuracy of a simple crystal oscillator is sufficient for most of our needs and most amateur equipment relies on this technique. For a discussion of crystal oscillators and temperature compensation, look in the **Oscillators** chapter of this book.

The second level of accuracy is achieved when the temperature around the crystal is stabilized, either by an “oven” or other nearby components. Crystals are usually designed to stabilize at temperatures far above any reached in normal operating environments. These oscillators are commonly good to 0.1 ppm per day and are widely used in the commercial

two-way radio industry.

The third accuracy level uses a double oven with proportional heating. The two ovens compensate for each other automatically and provide excellent temperature stability. The ovens must be left on continuously, however, and warm-up requires several days to two weeks.

Crystal *aging* also affects frequency stability. Some crystals change frequency over time (age) so the circuit containing the crystal must contain components to compensate for this change. Other crystals become more stable over time and become excellent frequency standards. Many commercial laboratories go to the expense of buying and testing several examples of the same oscillator and select the best one for use. As a result, many surplus oscillators are surplus for a reason. Nevertheless, a good stable crystal oscillator can be accurate to  $1 \times 10^{-9}$  per day and very appropriate for amateur applications.

### Time and Frequency Calibration

Many hams have digital frequency counters, which range from surplus lab equipment to new highly integrated instruments with nearly everything on one chip. Almost all of these are very precise and display nine or more digits. Many are even quite stable. Nonetheless, a 10-MHz oscillator accurate to 1 ppm per month can vary  $\pm 10$  Hz in one month. This drift rate may be acceptable for many applications, but the question remains: How accurate is it?

This question can be answered by calibrating the oscillator. There are several ways to perform this calibration. The most accurate method compares the unit in

question by leaving the oscillator operating, transporting it to an oscillator of known frequency and then making a comparison. A commonly used comparison method connects the output of the calibrated oscillator into the horizontal input of a high frequency oscilloscope, and the oscillator to be measured to the vertical input. It helps, but they need not be on the same frequency. By noting how long it takes the sine wave to travel one division at a given sweep speed, one can calculate the resulting drift in parts per million per minute (ppm/min).

Another technique of oscillator calibration uses a VLF phase comparator. This is a special direct-conversion receiver that picks up the signal from WWVB on 60 kHz. Phase comparison is used to compare WWVB with the divided frequency of the oscillator being tested. Many commercial units have a small strip chart printer attached and switches to determine the receiver frequency. Since these 60-kHz VLF Comparator receivers have been largely replaced by units that use Loran signals or rubidium standards, they can be found at very reasonable prices. A very effective 60-kHz antenna can be made by attaching an audio transformer with the low-impedance winding connected to the receiver antenna terminals by way of a series dc blocking capacitor. The high-impedance winding is then connected between ground and a random length of wire. A typical VLF Comparator can track an oscillator well into a few parts in  $10^{-10}$ . This technique directly compares the oscillator with an NIST standard and can even characterize oscillator drift characteristics in ppm per day or week.

Another fairly direct method compares an oscillator with one of the WWV HF signals. The received signal is not immensely accurate, but if the oscillator of a modern HF transceiver is carefully compared, it will be accurate enough for all but the most demanding work.

The last and least accurate way to calibrate an oscillator is to compare it with another oscillator or counter owned by you or another local ham. Unless the calibration of the other oscillator or counter is known, this comparison could be very misleading. True accuracy is not determined by the label of a famous company or impressive looks. Metrologists (people who calibrate and measure equipment) spend more time calibrating oscillators than any other piece of equipment.

# DC Instruments and Circuits

This section discusses the basics of analog and digital dc meters. It covers the design of range extenders for current, voltage and resistance; construction of a simple meter; functions of a digital voltmeter (DVM) and procedures for accurate measurements.

## Basic Meters

In measuring instruments and test equipment suitable for amateur purposes, the ultimate readout is generally based on a measurement of direct current. There are two basic styles of meters: analog meters that use a moving needle display, and digital meters that display the measured values in digital form. The analog meter for measuring dc current and voltage uses a magnet and a coil to move a pointer over a calibrated scale in proportion to the current flowing through the meter.

The most common dc analog meter is the D'Arsonval type, consisting of a coil of wire to which the pointer is attached so that the coil moves (rotates) between the poles of a permanent magnet. When current flows through the coil, it sets up a magnetic field that interacts with the field of the magnet to cause the coil to turn. The

design of the instrument normally makes the pointer move in direct proportion to the current.

## Digital Multimeters

In recent years there has been a flood of inexpensive digital multimeters (DMMs) ranging from those built into probes to others housed in large enclosures. They are more commonly referred to as digital voltmeters (DVMs) even though they are multimeters; they usually measure voltage, current and resistance. After some years of refining circuits such as the "successive approximation" and "dual slope" methods, most meters now use the dual-slope method to convert analog voltages to a digital reading. DVMs have basically three main sections as shown in Fig 26.1.

The first section scales the voltage or current to be measured. It has four main circuits:

- a chain of multiplier resistors that reduce the input voltage to 0-1 V,
- a converter that changes 0-1 V ac to dc,
- an amplifier that raises signals in the 0-100 mV range to 0-1 V and
- a current driver that provides a constant

current to the multiplier chain for resistance measurements.

The second section is an integrator. It is usually based on an operational amplifier that is switched by a timing signal. The timing signal initially shorts the input of the integrator to provide a zero reference. Next a reference voltage is connected to charge the capacitor for a determined amount of time. Finally the last part of the timing cycle allows the capacitor to discharge. The time it takes the capacitor to discharge is proportional to either the input voltage ( $V_{in}$ , after it was scaled into the range of 0 to 1 V) or 1 minus  $V_{in}$ , depending on the meter design. This discharge time is measured by the next section of the DVM, which is actually a frequency counter. Finally, the output of the frequency counter is scaled to the selected range of voltage or current and sent to the final section of the DVM — the digital display.

Since the timing is quite fast and the capacitor is not used long enough to drift much in value, the components that most determine accuracy are the reference voltage source and the range multiplier resis-

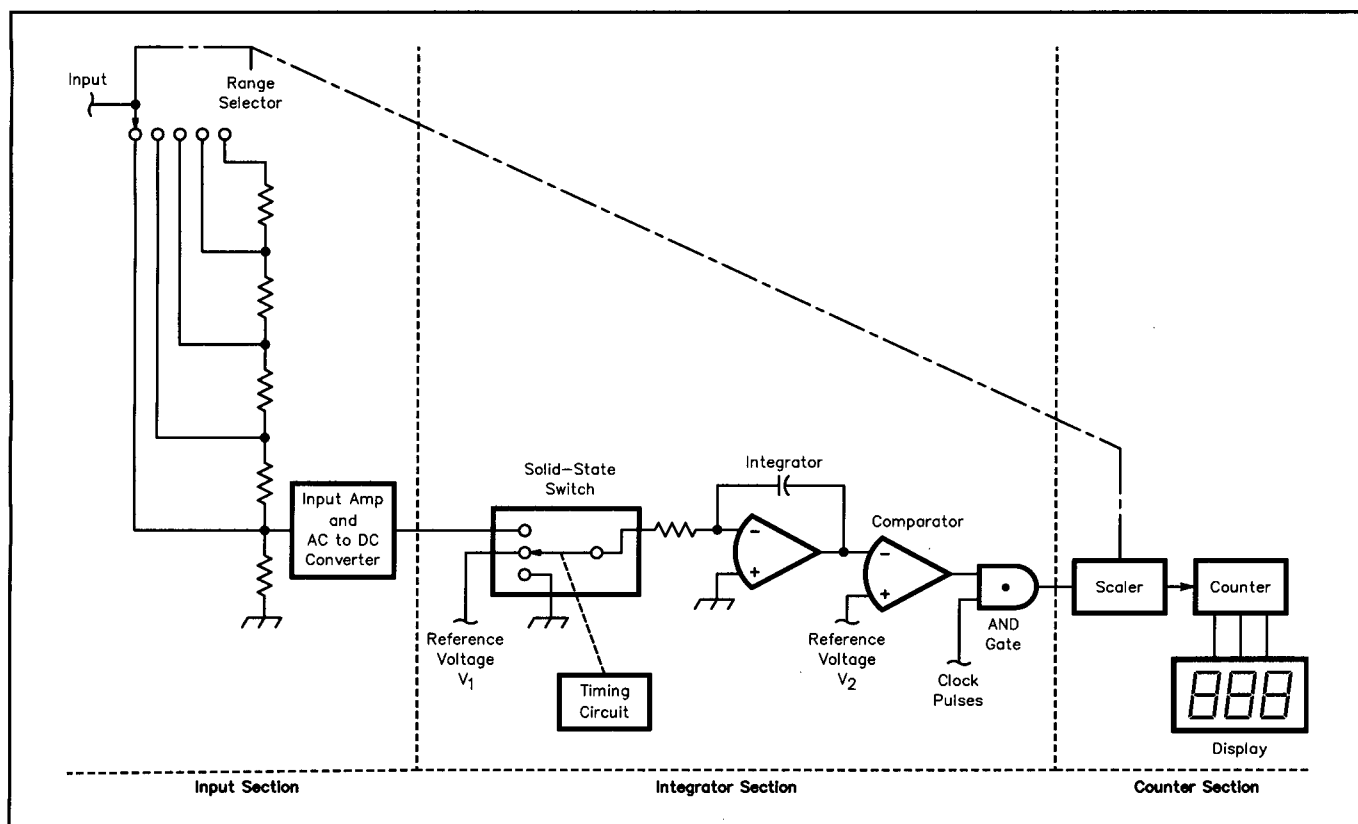

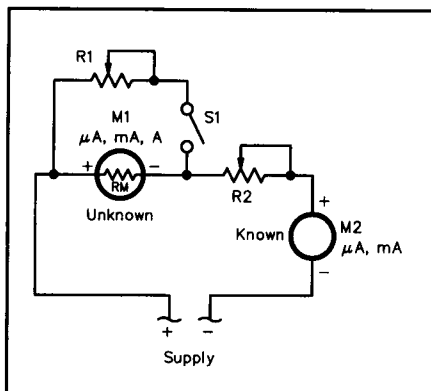

Fig 26.1 — A typical digital voltmeter consists of three parts: the input section for scaling, an integrator to convert voltage to pulse count, and a counter to display the pulse count representing the measured quantity.

**Fig 26.2 — This test setup allows safe measurement of a meter's internal resistance. See text for the procedure and part values.**

tors. With the availability of integrated resistor networks that are deposited or diffused onto the same substrate, drift is automatically compensated because all branches of a divider drift in the same direction simultaneously. The voltage sources are generally Zener diodes on substrates with accompanying series resistors. Often the resistor and Zener have opposite temperature characteristics that cancel each other. In more complex DVMs, extensive digital circuitry can insert values to compensate for changes in the circuit and can even be automatically calibrated remotely in a few moments.

Liquid crystal displays (LCD) are commonly used for commercial DVMs. As a practical matter they draw little current and are best for portable and battery-operated use. The usual alternative, light emitting diode (LED) displays, draw much more current but are better in low-light environments. Some older surplus units use gas plasma displays (orange-colored digits). You may have seen plasma displays on gas-station pumps. They are not as bright as LEDs, but are easier to read. On the down side, plasma displays require high-voltage power supplies, draw considerable current and often fail after 10 years or so.

The advantages of DVMs are high input resistance (10 MΩ on most ranges), accurate and precise readings, portability, a wide variety of ranges and low price. There is one disadvantage, however: Digital displays update rather slowly, often only one to two times per second. This makes it very difficult to adjust a circuit for a peak (maximum) or null (minimum) response using only a digital display. The changing digits do not give any clue of the measurement

trend and it is easy to tune through the peak or null between display updates. In answer, many new DVMs are built with an auxiliary bar-graph display that is updated constantly, thus providing instantaneous readings of relative value and direction of changes.

### Current Ranges

The sensitivity of an analog meter is usually expressed in terms of the current required for full-scale deflection of the pointer. Although a very wide variety of ranges is available, the meters of interest in amateur work give maximum deflection with currents measured in microamperes or milliamperes. They are called microammeters and milliammeters, respectively.

Thanks to the relationships between current, voltage and resistance expressed by Ohm's Law, it is possible to use a single low-range instrument (for example, 1 mA or less for full-scale pointer deflection) for a variety of direct-current measurements. Through its ability to measure current, the instrument can also be used indirectly to measure voltage. In the same way, a measurement of both current and voltage will obviously yield a value of resistance. These measurement functions are often combined in a single instrument: the volt-ohm-milliammeter or VOM, a multirange meter that is one of the most useful pieces of test equipment an amateur can possess.

### Accuracy

The accuracy of a D'Arsonval-move-ment dc meter is specified by the manufacturer. A common specification is  $\pm 2\%$  of full scale, meaning that a 0-100  $\mu\text{A}$  meter, for example, will be correct to within 2  $\mu\text{A}$  at any part of the scale. There are very few cases in amateur work where accuracy greater than this is needed. When the instrument is part of a more complex measuring circuit, however, the design and components can each cause error that accumulates to reduce the overall accuracy.

### Extending Current Range

Because of the way current divides between two resistances in parallel, it is possible to increase the range (more specifically to decrease the sensitivity) of a dc current meter. The meter itself has an inherent resistance (its internal resistance) which determines the full-scale current passing through it when its rated voltage is applied. (This rated voltage is on the order of a few millivolts.) When an external resistance is

connected in parallel with the meter, the current will divide between the two and the meter will respond only to that part of the current that flows through its movement. Thus, it reads only part of the total current; the effect makes more total current necessary for a full-scale meter reading. The added resistance is called a "shunt."

We must know the meter's internal resistance before we can calculate the value for a shunt resistor. Internal resistance may vary from a fraction of an ohm to a few thousand ohms, with greater resistance values associated with greater sensitivity. When this resistance is known, it can be used in the formula below to determine the required shunt for a given multiplication:

$$R = \frac{R_m}{n - 1} \quad (1)$$

where

$R$  = shunt resistance, ohms

$R_m$  = meter internal resistance, ohms

$n$  = the factor by which the original meter scale is to be multiplied.

Often the internal resistance of a particular meter is unknown (when the meter is purchased at a flea market or is taken from a commercial piece of equipment, for example). Unfortunately, the internal resistance of a meter cannot be measured directly with an ohmmeter without risk of damage to the meter movement.

Fig 26.2 shows a method to safely measure the internal resistance of a meter. It requires a calibrated meter that can measure the same current as the unknown meter. The system works as follows:  $S_1$  is switched off and  $R_2$  is set for maximum resistance. A supply of constant voltage is connected to the supply terminals (a battery will work fine) and  $R_2$  is adjusted so that the unknown meter reads exactly full scale. Note the current shown on  $M_2$ . Close  $S_1$  and alternately adjust  $R_1$  and  $R_2$  so that the unknown meter ( $M_1$ ) reads exactly half scale and the known meter ( $M_2$ ) reads the same value as in the step above. At this point, half of the current in the circuit flows through  $M_1$  and half through  $R_1$ . To determine the internal resistance of the meter, simply open  $S_1$  and read the resistance of  $R_1$  with an ohmmeter.

The values of  $R_1$  and  $R_2$  will depend on the meter sensitivity and the supply voltage. The maximum resistance value for  $R_1$  should be approximately twice the expected internal resistance of the meter. For highly sensitive meters (10  $\mu\text{A}$  and less),

1 k $\Omega$  should be adequate. For less-sensitive meters, 100  $\Omega$  should suffice. Use no more supply voltage than necessary.

The value for minimum resistance at R2 can be calculated using Ohm's Law. For example, if the meter reads 0 to 1 mA and the supply is a 1.5-V battery, the minimum resistance required at R2 will be:

$$R_2 = \frac{1.5}{0.001}$$

$$R_2(\text{min}) = 1500 \Omega$$

In practice a 2- or 2.5-k $\Omega$  potentiometer would be used.

### Making Shunts

Homemade shunts can be constructed from several kinds of resistance wire or from ordinary copper wire if no resistance wire is available. The copper wire table in the **Component Data** chapter of this *Handbook* gives the resistance per 1000 ft for various sizes of copper wire. After computing the resistance required, determine the smallest wire size that will carry the full-scale current, again from the wire table. Measure off enough wire to give the required resistance. A high-resistance 1- or 2-W carbon-composition resistor makes an excellent form on which to wind the wire, as the high resistance does not affect the value of the shunt. If the shunt gets too hot, go to a larger diameter wire of a greater length.

### VOLTMETERS

If a large resistance is connected in series with a meter that measures current, as shown in Fig 26.3, the current multiplied by the resistance will be the voltage drop across the resistance. This is known as a multiplier. An instrument used in this way is calibrated in terms of the voltage drop across the multiplier resistor and is called a voltmeter.

### Sensitivity

Voltmeter sensitivity is usually expressed in ohms per volt ( $\Omega/V$ ), meaning that the meter full-scale reading multiplied by the sensitivity will give the total resistance of the voltmeter. For example, the resistance of a 1 k $\Omega/V$  voltmeter is 1000 times the full-scale calibration voltage. Then by Ohm's Law the current required for full-scale deflection is 1 milliamperere. A sensitivity of 20 k $\Omega/V$ , a commonly used value, means that the instrument is a 50- $\mu A$  meter.

As voltmeter sensitivity (resistance) increases, so does accuracy. Greater meter

resistance means that less current is drawn from the circuit and thus the circuit under test is less affected by connection of the meter. Although a 1000- $\Omega/V$  meter can be used for some applications, most good meters are 20 k $\Omega/V$  or more. Vacuum-tube voltmeters (VTVMs) and their modern equivalent FET voltmeters (FETVOMs) are usually 10-100 M $\Omega/V$  and DVMs can go even higher.

### Multipliers

The required multiplier resistance is found by dividing the desired full-scale voltage by the current, in amperes, required for full-scale deflection of the meter alone. To be mathematically correct, the internal resistance of the meter should be subtracted from the calculated value. This is seldom necessary (except perhaps for very low ranges) because the meter resistance is usually very low compared with the multiplier resistance. When the instrument is already a voltmeter with an internal multiplier, however, the meter resistance is significant. The resistance required to extend the range is then:

$$R = R_m (n - 1) \quad (2)$$

where

$R_m$  = total resistance of the instrument  
 $n$  = factor by which the scale is to be multiplied

For example, if a 1-k $\Omega/V$  voltmeter having a calibrated range of 0 to 10 V is to be extended to 1000 V,  $R_m$  is  $1000 \times 10 = 10 \text{ k}\Omega$ ,  $n$  is  $1000/10 = 100$  and  $R = 10,000 \times (100 - 1) = 990 \text{ k}\Omega$ .

When extending the range of a voltmeter or converting a low-range meter into a voltmeter, the rated accuracy of the instrument is retained only when the multiplier resistance is precise. High-precision, hand-made and aged wire-wound resistors are used as multipliers of high-quality instruments. These are relatively expensive, but the home constructor can do well with 1% tolerance metal-film resistors. They should be derated when used for this purpose. That is, the actual power dissipated in the resistor should not be more than  $1/10$  to  $1/4$  the rated dissipation. Also, use care to avoid overheating the resistor body when soldering. These precautions will help prevent permanent change in the resistance of the unit.

Many DVMs use special resistor groups that have been etched on quartz or sapphire and laser trimmed to value. These resistors are very stable and often quite accurate. They can be bought new from various suppliers. It is also possible to "rescue" the divider/multiplier resistors

**Fig 26.3 — A voltmeter is constructed by placing a current-indicating instrument in series with a high resistance, the "multiplier."**

from an older DVM that no longer functions and use them as multipliers. Look for a series of four or five resistors that add up to 10 M $\Omega$ : 9,9,90,900,9,000,90,000 and 900,000  $\Omega$ . There is usually another 1-M $\Omega$  resistor in series to isolate the meter from the circuit under test. A few of these high-accuracy resistors in "odd" values can help calibrate less-expensive instruments.

### DC Voltage Standards

For a long time NIST has statistically compared a bank of special Weston Cell or cadmium sulfate batteries to arrive at the standard volt. By using a special tapped resistor, a 1.08-V battery can be compared to other voltages and instruments compared. However, these are very high-impedance batteries that deliver almost no current and are relatively temperature sensitive. They are made up of a solution of cadmium and mercury in opposite legs of an "H" shaped glass container. You can read much more about them in *Calibration—Philosophy and Practice*, published by the John Fluke Co of Mount Lake Terrace, Washington.

Hams often use an ordinary flashlight battery as a convenient voltage reference. A fresh D cell usually provides 1.56 V under no load, as would be measured by a DVM. The Heath Company, which supplied thousands of kits to the ham community for many years, used such batteries as the calibration references for many of their kits.

Recently, NIST has been able to use a microwave to voltage converter called a "Josephson Junction" to determine the value of the volt. The converter transfers the accuracy of a frequency standard to the accuracy of the voltage that comes out of it. The converter generates only 5 mV, however, which then must be scaled to the standard 1-V level. One problem with high-accuracy measurements is stray noise (low-level voltages) that creates a floor below which measurements are

**Fig 26.4 — A voltmeter can be used to measure current as shown. For reasonable accuracy, the shunt should be 5% of the circuit impedance or less, and the meter resistance should be 20 times the circuit impedance or more.**

**Fig 26.5 — Power or resistance can be calculated from voltage and current measurements. At A, error introduced by the ammeter is dominant. At B, error introduced by the voltmeter is dominant. The text gives an example.**

meaningless. For that reason, meters with five or more digits must be very quiet and any comparisons must be made at a voltage high enough to be above the noise.

## DC MEASUREMENT CIRCUITS

### Current Measurement with a Voltmeter

A current-measuring instrument should have very low resistance compared with the resistance of the circuit being mea-

sured; otherwise, inserting the instrument will alter the current from its value when the instrument is removed. The resistance of many circuits in radio equipment is high and the circuit operation is affected little, if at all, by adding as much as a few hundred ohms in series. [Even better, use a resistor that is part of the working circuit if one exists. Unsolder one end of the resistor, measure its resistance, reinstall it and then make the measurement.—Ed.] In such cases the voltmeter method of measuring current in place of an ammeter, shown in Fig 26.4, is frequently convenient. A voltmeter (or low-range milliammeter provided with a multiplier and operating as a voltmeter) having a full-scale voltage range of a few volts is used to measure the voltage drop across a suitable value of resistance acting as a shunt.

The value of shunt resistance must be calculated from the known or estimated maximum current expected in the circuit (allowing a safe margin) and the voltage required for full-scale movement of the meter with its multiplier. For example, to measure a current estimated at 15 A on the 2-V range of a DVM, we need to solve Ohm's Law for the value of R:

$$R_{\text{shunt}} = \frac{2 \text{ V}}{15 \text{ A}} = 0.133 \Omega$$

This resistor would dissipate  $15^2 \times 0.133 = 29.92 \text{ W}$ . For a short-duration measurement, 30 1.0- $\Omega$ , 1-W resistors could be parallel connected in two groups of 15 (0.067  $\Omega$  per group) that are series connected to yield 0.133  $\Omega$ . For long-duration measurements, 2- to 5-W resistors would be better.

### Power

Power in direct-current circuits is usually determined by measuring the current and voltage. When these are known, the power can be calculated by multiplying voltage, in volts, by the current, in amperes. If the current is measured with a milliammeter, the reading of the instrument must be divided by 1000 to convert it to amperes.

The setup for measuring power is shown in Fig 26.5A, where R is any dc load, not necessarily an actual resistor. In this measurement it is always best to use the lowest voltmeter or ammeter scale that allows reading the measured quantity. This results in the percentage error being less than if the meter was reading in the very lowest part of the selected scale.

### Resistance

If both voltage and current are measured in a circuit such as that in Fig 26.5, the value of resistance R (in case it is un-

known) can be calculated from Ohm's Law. For reasonable results, two conditions should be met:

1. The internal resistance of the current meter should be less than 5% of the circuit resistance.
2. The input impedance of the voltmeter should be greater than 20 times the circuit resistance.

These conditions are important because both meters tend to load the circuit under test. The current meter resistance adds to the unknown resistance, while the voltmeter resistance decreases the unknown resistance as a result of their parallel connection.

### Ohmmeters

Although Fig 26.5B suffices for occasional resistance measurements, it is inconvenient when we need to make frequent measurements over a wide range of resistance. The device generally used for this purpose is the ohmmeter. Its simplest form is a voltmeter (or milliammeter, depending on the circuit used) and a small battery. The meter is calibrated so that the value of an unknown resistance can be read directly from the scale. Fig 26.6 shows some typical ohmmeter circuits. In the simplest circuit, Fig 26.6A, the meter and battery are connected in series with the unknown resistance. If a given movement of the meter's needle is obtained with terminals A-B shorted, inserting the resistance to be measured will cause the meter reading to decrease. When the resistance of the voltmeter is known, the following formula can be applied.

$$R = \frac{eR_m}{E} - R_m \quad (3)$$

where

R = unknown resistance, ohms

e = voltage applied (A-B shorted)

E = voltmeter reading with R connected

R<sub>m</sub> = resistance of the voltmeter.

The circuit of Fig 26.6A is not suited to measuring low values of resistance (less than 100  $\Omega$  or so) with a high-resistance voltmeter. For such measurements the circuit of Fig 26.6B is better. The unknown resistance is

$$R = \frac{I_2 R_m}{I_1 - I_2} \quad (4)$$

where

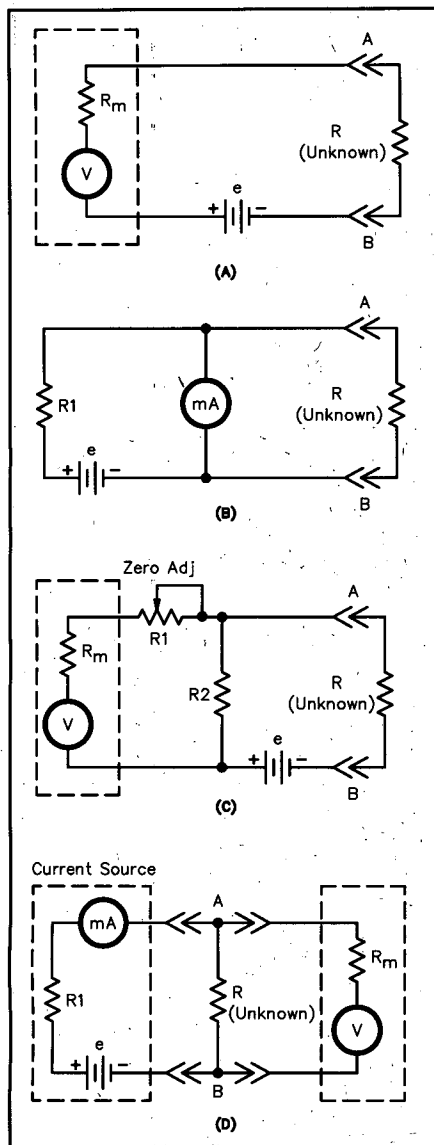

R = unknown resistance, ohms

R<sub>m</sub> = the internal resistance of the milliammeter, ohms

I<sub>1</sub> = current with R disconnected from terminals A-B, amps

I<sub>2</sub> = current with R connected, amps.

**Fig 26.6 — Here are several kinds of ohmmeters. Each is explained in the text.**

This formula is based on the assumption that the current in the complete circuit will be essentially constant whether or not the unknown terminals are short circuited. This requires that  $R_1$  be much greater than  $R_m$ . For example,  $3000\ \Omega$  for a 1-mA meter with an internal resistance of perhaps  $50\ \Omega$ . In this case, a 3-V battery would be necessary in order to obtain a full-scale deflection with the unknown terminals open.  $R_1$  can be an adjustable resistor, to permit setting the open-terminal current to exact full scale.

A third circuit for measuring resistance is shown in Fig 26.6C. In this case a high-resistance voltmeter is used to measure the voltage drop across a reference resistor,  $R_2$ , when the unknown resistor is connected so that current flows through it,  $R_2$  and the battery in series. With suitable  $R_2$ s

(low values for low-resistance, high values for high-resistance unknowns), this circuit gives equally good results for resistance values in the range from one ohm to several megohms. The voltmeter resistance,  $R_m$ , must be much greater (50 times or more) than that of  $R_2$ . A 20-k $\Omega$ /V instrument (50- $\mu$ A movement) is generally used. If the current through the voltmeter is negligible compared with the current through  $R_2$ , the formula for the unknown is

$$R = \frac{eR_2}{E} - R_2 \quad (5)$$

where

$R$  and  $R_2$  are in ohms

$e$  = voltmeter reading with  $R$  removed and  $A$  shorted to  $B$ ;

$E$  = voltmeter reading with  $R$  connected.

$R_1$  sets the voltmeter reading exactly to full scale when the meter is calibrated in ohms. A 10-k $\Omega$  pot is suitable with a 20-k $\Omega$ /V meter. The battery voltage is usually 3 V for ranges to 100 k $\Omega$  and 6 V for higher ranges.

#### Four-Wire Resistance Measurements

In situations where a very low resistance, like a 50- $\Omega$  dummy load, is to be measured, the resistance of the test leads can be significant. The average lead resistance is about 0.9  $\Omega$  through both leads, which would make a 50.5- $\Omega$  dummy load appear to be 51.4  $\Omega$ . To compensate for lead resistance, some meters allow for four-wire measurements. Briefly, two wires from the current source and two wires from the measuring circuit exit the meter case separately and connect directly to the unknown resistance (see Fig 26.6D). This eliminates the voltage drop in the current-source leads from the measurement. In practice, four-wire systems use special test clips that are similar to alligator clips, except that the jaws are insulated from each other and a meter lead is attached to each jaw. In some meters, an additional control allows the operator to short the test leads together and adjust the meter for a zero reading before making low-resistance measurements.

#### Bridge Circuits

Bridges are an important class of measurement circuits. They perform measurement by comparison with some known component or quantity, rather than by direct reading. VOMs, DVMs and other meters are convenient, but their accuracy is limited. The accuracy of manufactured analog meters is determined at the factory, while digital meters are accurate only to

some percentage  $\pm 1$  in the least-significant digit. The accuracy of comparison measurements, however, is determined only by the comparison standard and bridge sensitivity.

Bridge circuits are useful across most of the frequency spectrum. Most amateur applications are at RF, as shown later in this chapter. The principles of bridge operation are easier to understand at dc, however, where bridge operation is simple.

#### The Wheatstone Bridge

A simple resistance bridge, known as the Wheatstone bridge, is shown in Fig 26.7. All other bridge circuits are based on this design. The four resistors,  $R_1$ ,  $R_2$ ,  $R_3$  and  $R_4$  in Fig 26.7A, are known as the bridge arms. For the voltmeter reading to be zero (null) the voltage dividers consisting of the pairs  $R_1$ - $R_3$  and  $R_2$ - $R_4$  must be equal. This means

$$\frac{R_1}{R_3} = \frac{R_2}{R_4} \quad (6)$$

When this occurs the bridge is said to be *balanced*.

The circuit is usually drawn as shown at Fig 26.7B when used for resistance measurement. Equation 6 can be rewritten

$$RX = RS \left( \frac{R_2}{R_1} \right) \quad (7)$$

$RX$  is the unknown resistor.  $R_1$  and  $R_2$  are usually made equal; then the calibrated adjustable resistance (the standard),  $RS$ , will have the same value as  $RX$  when  $RS$  is set to show a null on the voltmeter.

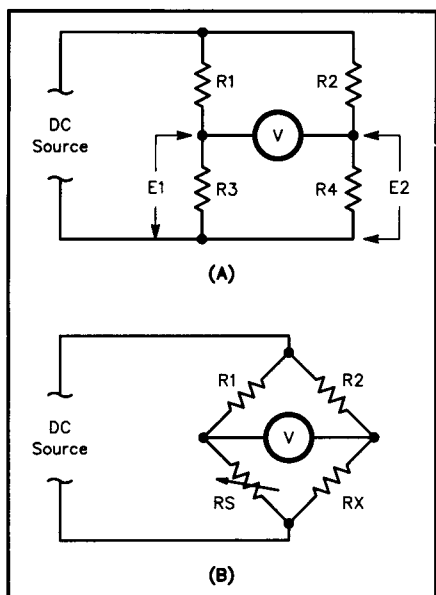

Note that the resistance ratios, rather than the actual resistance values, determine the voltage balance. The values do have important practical effects on the sensitivity and power consumption, however. Bridge sensitivity is the ability of the meter to respond to slight unbalance near the null point; a sharper null means a more accurate setting of  $RS$  at balance.

The Wheatstone bridge is rarely used by amateurs for resistance measurement, since it is easier to measure resistances with VOMs and DVMs. Nonetheless, it is worthwhile to understand its operation as the basis of more complex bridges.

#### ELECTRONIC VOLTMETERS

We have seen that the resistance of a simple voltmeter (as in Fig 26.3) must be extremely high in order to avoid "loading" errors caused by the current that necessarily flows through the meter. The use of high-resistance meters tends to cause difficulty in measuring relatively low voltages because multiplier resistance progressively lessens as the voltage range is lowered.

Voltmeter resistance can be made inde-

**Fig 26.7 — A Wheatstone bridge circuit. A bridge circuit is actually a pair of voltage dividers (A). B shows how bridges are normally drawn.**

pendent of voltage range by using vacuum tubes, FETs or op amps as dc amplifiers between the circuit under test (CUT) and the indicator, which may be a conventional meter movement or a digital display. Because the input resistance of the electronic devices mentioned is extremely high (hundreds of megohms) they have negligible loading effect on the CUT. They do, however, require a closed dc path in their input circuits (although this path can have very high resistance). They are also limited in the voltage level that their input circuits can handle. Because of this, the device

actually measures a small voltage across a portion of a high-resistance voltage divider connected to the CUT. Various voltage ranges are obtained from appropriate taps on the voltage divider.

In the design of electronic voltmeters it has become standard practice to use a voltage divider with a total resistance of  $10\text{ M}\Omega$ , tapped as required, in series with a  $1\text{-M}\Omega$  resistor incorporated in the meter. The total voltmeter resistance, including probe, is therefore  $11\text{ M}\Omega$ . The  $1\text{-M}\Omega$  resistor serves to isolate the voltmeter circuit from the CUT.

## AC Instruments and Circuits

Most ac measurements differ from dc measurements in that the accuracy of the measurement depends on the purity of the sine wave. It is fairly easy to measure an ac voltage to between 1% and 5%, but getting down to 0.01% is difficult. Measurements to less than 0.01% must be left to precision laboratories. In general, amateurs measure ac voltages in household circuits, audio stages and RF power measurements, and 1% to 5% accuracy is usually close enough.

This section covers basic measurements, the nature of sine waves and meters. There are four common ways to measure ac voltage:

- Use a rectifier to change the ac to dc and then measure the dc.
- Heat a resistor in a Wheatstone bridge with the ac and measure the bridge unbalance.
- Heat a resistor surrounded by oil and measure the temperature rise.
- Use electronic circuits (such as multipliers and logarithmic amplifiers) with mathematical ac-to-dc conversion formulas. This method is not common, but it's interesting.

### Calorimetric Meters

In a calorimetric meter, power is ap-

plied to a resistor that is immersed in the flow path of a special oil. This oil transfers the heat to another resistor that is part of a bridge. As the resistor heats, its resistance changes and the bridge becomes unbalanced. An attached meter registers the unbalance of the bridge as ac power. This type of meter is accurate for both dc and ac. They frequently operate from dc well into the GHz range. For calibration, an accurate dc voltage is applied and the reading is noted; a similar ac voltage is applied and the readings are compared. Some calorimetric meters are complicated, but others are simple.

### Thermocouple Meters and RF Ammeters

In a thermocouple meter, alternating current flows through a low-resistance heating element. The power lost in the resistance generates heat that warms a thermocouple, which consists of a pair of junctions of two different metals. When one junction is heated a small dc voltage is generated in response to the difference in temperature of the two junctions. This voltage is applied to a dc milliammeter that is calibrated in suitable ac units. The heater-thermocouple/dc-meter combination is usually housed

in a regular meter case.

Thermocouple meters are available in ranges from about 100 mA to many amperes. Their useful upper frequency limit is in the neighborhood of 100 MHz. Amateurs use these meters mostly to measure current through a known load resistance and calculate the RF power delivered to the load.

## RECTIFIER INSTRUMENTS

The response of a rectifier RF ammeter is proportional (depending on the design) to either the peak or average value of the rectified ac wave, but never directly to the RMS value. These meters cannot be calibrated in RMS without knowing the relationship that exists between the real reading and the RMS value. This relationship may not be known for the circuit under test.

Average-reading ac meters work best with pure sine waves and RMS meters work best with complicated wave forms. Since many practical measurements involve nonsinusoidal forms, it is necessary to know what your instrument is actually reading, in order to make measurements intelligently. Most VOMs and VTVMs use averaging techniques, while DVMs may use either one. In all cases, check the meter instruction

manual to be sure what it reads.

### Peak and Average with Sine-Wave Rectification

Peak, average and RMS values of ac waveforms are discussed in the **AC Theory** chapter. Because the positive and negative half cycles of the sine wave have the same shape, half-wave rectification of either the positive half or the negative half gives exactly the same result. With full-wave rectification, the peak reading is the same, but the average reading is doubled, because there are twice as many half cycles per unit of time.

### Asymmetrical Wave Forms

A nonsinusoidal waveform is shown in **Fig 26.8A**. When the positive half cycles are rectified, the peak and average values are shown at B. If the polarity is reversed and the negative half cycles are rectified, the result is shown in **Fig 26.8C**. Full-wave rectification of such a lopsided wave changes the average value, but the peak reading is always the same as that of the half cycle that produces the highest peak in half-wave rectification.

### Effective-Value Calibration

The actual scale calibration of commercially made rectifier voltmeters is very often (almost always, in fact) in terms of RMS values. For sine waves, this is satisfactory and useful because RMS is the standard measurement at power-line frequencies. It is also useful for many RF applications when the waveform is close to sinusoidal. In other cases, particularly in the AF range, the error may be considerable when the waveform is not pure.

### Turn-Over

From **Fig 26.8** it is apparent that the calibration of an average-reading meter will be the same whether the positive or negative sides are rectified. A half-wave peak-reading instrument, however, will indicate different values when its connections to the circuit are reversed (turn-over effect). Very often readings are taken both ways, in which case the sum of the two is the peak-to-peak (P-P) value, a useful figure in much audio and video work.

### Average- vs Peak-Reading Circuits

For traditional analog displays, the basic difference between average- and peak-reading rectifier circuits is that the output is not filtered for averaged readings, while a filter capacitor is charged to the peak value of the output voltage in order to measure peaks. **Fig 26.9A** and **B** show typical average-reading circuits, one half-wave and the other full-wave. In the ab-

sence of dc filtering, the meter responds to wave forms such as those shown at B, C and D in **Fig 26.8**; and since the inertia of the pointer system makes it unable to follow the rapid variations in current, it averages them out mechanically.

In **Fig 26.9A**, D1 actuates the meter; D2 provides a low-resistance dc return in the meter circuit on the negative half cycles. R1 is the voltmeter multiplier resistance. R2 forms a voltage divider with R1 (through D1) that prevents more than a few ac volts from appearing across the rectifier-meter combination. A corresponding resistor can be used across the full-wave bridge circuit.

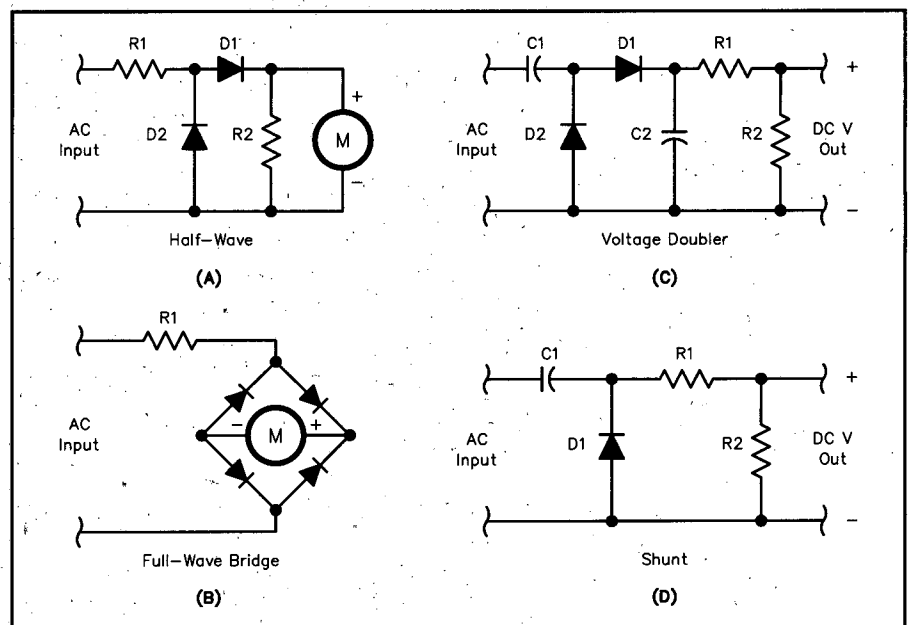

In these two circuits there is no provision to isolate the meter from any dc voltage in the circuit under test. The resulting errors can be avoided by connecting a large nonpolarized capacitor in series with the hot lead. The reactance must be low compared with the meter impedance (at the lowest frequency of interest, more on this later) in order for the full ac voltage to be applied to the meter circuit. Some meters may require as much as 1  $\mu\text{F}$  at line (60 Hz) frequencies. Such capacitors are usually not included in VOMs.

Voltage doubler and shunt peak-reading circuits are shown in **Fig 26.9C** and **D**. In both circuits, C1 isolates the rectifier from dc voltage in the circuit under test. In the voltage-doubler circuit, the time constant of the C2-R1-R2 combination must be very large compared with the period of the lowest ac frequency to be measured; similarly with C1-R1-R2 in the shunt cir-

cuit. This is so because the capacitor is charged to the peak value ( $V_{P-P}$  in C,  $V_P$  in D) when the ac wave reaches its maximum and then must hold the charge (so it can register on a dc meter) until the next maximum of the same polarity. If the time constant is 20 times the ac period, the charge will have decreased by about 5% when the next charge occurs. The average voltage

**Fig 26.8—** Peak vs average ac values for an asymmetrical wave form. Note that the peak values are different with positive or negative half-cycle rectification.

**Fig 26.9 —** Half (A) and full-wave (B) bridge rectifiers for average-reading, analog-display meters. Peak-reading circuits: a voltage doubler (C) and a shunt circuit (D). All circuits are discussed in the text.

drop will be smaller, so the error is appreciably less. The error will decrease rapidly with increasing frequency (if there is no change in the circuit values), but it will increase at lower frequencies.

In Fig 26.9C and D,  $R_1$  and  $R_2$  form a voltage divider that reduces the voltage to some desired value. For example, if  $R_1$  is  $0\ \Omega$  in the voltage doubler, the voltage across  $R_2$  is approximately  $V_{p-p}$ ; if  $R_1 = R_2$ , the output is approximately  $V_p$  (as long as the waveform is symmetrical).

The most common application of the shunt circuit is an RF probe to read  $V_{RMS}$ . In that case,  $R_2$  is the input impedance of a VTVM or DVM:  $11\ M\Omega$ .  $R_1$  is chosen so that 71% of the peak value appears across

$R_2$ . This converts the peak reading to RMS for sine-wave ac.  $R_1$  is therefore approximately  $4.7\ M\Omega$ , making the total resistance nearly  $16\ M\Omega$ . A capacitance of  $0.05\ \mu F$  is sufficient for low audio frequencies under these conditions. Much smaller values of capacitance may be used at RF.

### Voltmeter Impedance

The impedance of a voltmeter at the frequency being measured may have an effect on the accuracy similar to that caused by the resistance of a dc voltmeter, as discussed earlier. The ac meter is a resistance in parallel with a capacitance. Since the capacitive reactance decreases with increasing frequency, the impedance also

decreases with frequency. The resistance does change with voltage level, particularly at very low voltages (10 V or less) depending on the sensitivity of the meter and the kind of rectifier used.

The ac load resistance represented by a diode rectifier is about one-half of its dc-load resistance. In Fig 26.9A the dc load is essentially the meter resistance, which is generally quite low compared with the multiplier resistance  $R_1$ . Hence, the total resistance will be about the same as the multiplier resistance. The capacitance depends on the components and construction, test-lead length and location, and other such factors. In general, the capacitance has little or no effect at lower line and audio frequencies, but ordinary VOMs lose accuracy at high audio frequencies and are of little use at RF. Rectifiers with very low inherent capacitance are used at RF and they are usually located at the probe tip to reduce losses.

Similar limitations apply to peak-reading circuits. In the shunt circuit, the resistive part of the impedance is smaller than in the voltage-doubler circuit because the dc load resistance,  $R_1/R_2$ , is directly across the circuit under test and in parallel with the diode ac load resistance. In both peak-reading circuits the effective capacitance may range from 1 or 2 to a few hundred pF, with 100 pF typical in most instruments.

### Scale Linearity

Fig 26.10 shows a typical current/voltage chart for a small semiconductor diode, which shows that the forward dynamic resistance of the diode is not constant, but rapidly decreases as the forward voltage increases from zero. The change from high to low resistance happens at much less than 1 V, but is in the range of voltage needed for a dc meter. With an average-reading circuit the current tends to be proportional to the square of the applied voltage. This makes the readings at the low end of the meter scale very crowded. For most measurement purposes, however, it is far more desirable for the output to be linear (that is, for the reading to be directly proportional to the applied voltage), which means that the markings on the meter are more evenly spaced.

To obtain that kind of linearity it is necessary to use a relatively large load resistance for the diode: Large enough that this resistance, rather than the diode resistance, will determine how much current flows. With this technique you can have a linear reading meter, but at the expense of sensitivity. The resistance needed depends on the type of diode;  $5\ k\Omega$  to  $50\ k\Omega$  is usually enough for a germanium rectifier,

## Sources for RF Ammeters

When it comes to getting your own RF ammeter, there's good news and bad news. First, the bad news. New RF ammeters are expensive: about \$70 to \$200 (in 1994). AM radio stations are the main users of these today. The FCC defines the output power of AM stations based on the RF current in the antenna, so new RF ammeters are made mainly for that market. They are quite accurate, and their prices reflect that.

The good news is that used RF ammeters are often available. For example, Fair Radio Sales (see the Address List in the **References** chapter) has been a consistent RF-ammeter source. Ham flea markets are also worth trying. Some grubbing around in your nearest surplus store or some older ham's junk box may provide just the RF ammeter you need.

### RF Ammeter Substitutes

Don't despair if you can't find a used RF ammeter. It's possible to construct your own. Both hot-wire and thermocouple units can be homemade.

Pilot lamps in series with antenna wires, or coupled to them in various ways, can indicate antenna current\* or even forward and reflected power.†

Another approach is to use a small low-voltage lamp as the heat/light element and use a photo detector driving a meter as an indicator. (Your eyes and judgment can serve as the indicating part of the instrument.) A feed-line balance checker could be as simple as a couple of lamps with the right current rating and the lowest voltage rating available. You should be able to tell fairly well by eye which bulb is brighter or if they are about equal. You can calibrate a lamp-based RF ammeter with 60-Hz or dc power.

As another alternative, you can build an RF ammeter that uses a dc meter to indicate rectified RF from a current transformer that you clamp over a transmission line wire.††

### Copper-Top Battery Testers as RF Ammeters

Finally, there are the *free* RF ammeters that come as the testers with Duracell batteries! These are actually 3 to 5- $\Omega$  resistors with built-in liquid-crystal displays. The resistor heats the liquid-crystal strip; the length of the "lighted" portion (heat turns the strip clear, exposing the fluorescent ink beneath) indicates the magnitude of the current.

Despite their "+" and "-" markings, these indicators are not polarized. Their resistance is low enough to have relatively little effect on a 50- $\Omega$  system. (For example, putting one in series with a 50- $\Omega$  dummy load would increase the system SWR from 1 to 1.1:1. These testers can measure about 200 to 400 mA. (You can achieve higher ranges by means of a shunt.) Best of all, if you burn out one of these "meters" during your tests, you can replace it at any drugstore, hardware store or supermarket for a few dollars, with some batteries thrown in free.

depending on the dc meter sensitivity, but several times as much may be needed for silicon diodes. Higher resistances require greater meter sensitivity; that is, the basic meter must be a microammeter rather than a low-range milliammeter.

### Reverse Current

When semiconductor diodes are reverse biased, a small leakage current flows. This reverse current flows during the half cycle when the diode should appear open, and the current causes an error in the dc meter reading. The quantity of reverse current is indicated by a diode's *back resistance* specification. This back resistance is so high that reverse current is negligible with silicon diodes, but back resistance may be less than 100 k $\Omega$  for germanium diodes.

The practical effect of semiconductor back resistance is to limit the amount of resistance that can be used in the dc load. This in turn affects the linearity of the meter scale. For practical purposes, the back resistance of vacuum-tube diodes is infinite.

### RF Voltage

Special precautions must be taken to minimize the capacitive component of the voltmeter impedance at RF. If possible, the rectifier circuit should be installed permanently at the point where the RF voltage is to be measured, using the shortest possible RF connections. The dc meter can be remotely located, however.

For general RF measurements an RF probe is used in conjunction with an 11 M $\Omega$  electronic voltmeter. The circuit of Fig 26.11, which is basically the shunt peak-reading circuit of Fig 26.9D, is gen-

**Fig 26.10 — Voltage vs current characteristics for a typical semiconductor diode. Actual values vary with different part numbers, but the forward current will always be increasing steeply with 1 V applied. Note that the forward current scale (mA) is 1000 times larger than that for reverse leakage current ( $\mu$ A). Breakdown voltage varies from 15 V to several hundred volts.**

erally used. The series resistor, which is installed in the probe close to the rectifier, prevents RF from being fed through the probe cable to the electronic voltmeter. (In addition, the capacitance of the coaxial cable serves as a bypass for any RF on the lead.) This resistor, in conjunction with the 10-M $\Omega$  divider resistance of the electronic voltmeter, reduces the peak rectified voltage to a dc value equivalent to the RMS of the RF signal. Therefore, the RF readings are consistent with the regular dc calibration.

Of the diodes readily available to ama-

**Fig 26.11 — At A is the schematic, at B a photo, of an RF probe for electronic voltmeters. The case of this probe is a seven-pin ceramic tube socket and a 2 1/4-inch tube shield. A grommet protects the cable where it leaves the tube shield, and an alligator clip on the cable braid connects the probe to the ground of the circuit under test.**

teurs, the germanium point-contact or Schottky diode is preferred for RF-probe applications. It has low capacitance (on the order of 1 pF) and in high-back-resistance Schottky diodes, the reverse current is not serious. The principal limitation is that its safe reverse voltage is only about 50 to 75 V, which limits the applied voltage to 15 or 20 V RMS. Diodes can be series connected to raise the overall rating. At RF, however, it is more common to use capacitors or resistors as voltage dividers and apply the divider output to a single diode.

## AN RF PROBE FOR ELECTRONIC VOLTMETERS

The circuit of Fig 26.11 can be built into a practical RF probe as shown in Figs 26.12 and 26.13. This vintage *Handbook* project requires a seven-pin miniature tube socket and a matching tube shield. Both of these items are likely to be found at a hamfest or flea market. Alternatively, the probe could be built dead-bug style on a small strip of PC board for insertion in a section of copper or brass tubing. If you like close work, build it into a PL-259 connector!

The isolation capacitor, C1, diode and filter/divider resistor are mounted on a bakelite five-lug terminal strip, as shown in Fig 26.13. Turn one end lug 90° so it

Fig 26.12 — A view inside the RF probe. The cable is RG-58 coax.

points off the end of the strip. Cut all other lugs off flush with the edge of the strip. Mount the small components close to the terminal strip, to keep lead lengths as short as possible and minimize stray capacitance. Use spaghetti tubing over all wires to prevent accidental shorts.

Where the inner conductor connects to the terminal lug, unravel the shield three-quarters of an inch, slip a piece of spaghetti tubing over it and then solder the

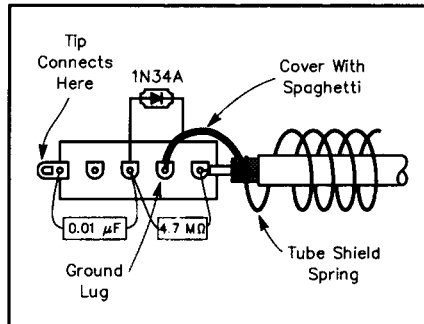

Fig 26.13 — Construction details of the RF probe tie strip. Leads are shown long here for clarity; keep them as short as possible when building.

braid to the ground lug on the terminal strip. Remove the spring from the tube shield, slide it over the cable and crimp it to the remaining exposed shield braid. Solder both the spring and a 12-inch length of flexible braid to the shield.

Next, cut off the pins of a seven-pin miniature shield-base tube socket. Use a socket with a cylindrical center post. Crimp the terminal lug that was bent out at the end of the strip and insert it into the center post of the tube socket from the top. Insert a pointed piece of heavy wire into the bottom of the tube socket center post and solder the lug and tip to the center post. Insert a half-inch grommet at the top of the tube shield and slide the shield over the cable and flexible braid down onto the tube socket. The spring should make good contact with the tube shield to assure that the probe case is grounded. Solder an alligator clip to the other end of the flexible braid and mount a suitable connector on the free end of the probe cable.

The accuracy of the probe is  $\pm 10\%$  from 50 kHz to 250 MHz. The approximate input impedance is 6 k $\Omega$  shunted by 1.75 pF (at 200 MHz).

## RF POWER

RF power can be measured by means of an accurately calibrated RF voltmeter connected across a dummy load in which the power is dissipated. If the load is a known pure resistance, the power, by Ohm's Law, is equal to  $E^2/R$ , where E is the RMS voltage.

### The Hewlett-Packard 410B/C VTVM

The Hewlett-Packard 410B and 410C VTVMs have been standards of bench measurement for industry, and they are now available as industrial surplus. These units are not only excellent VTVMs, but they are also good wide-range RF power meters. Both models use a vacuum-tube detector mounted in a low-loss probe for ac measurements. With an adapter that allows the probe to contact the center conductor of a transmission line, it will give very good RF voltage measurements from 1 mV to 300 V and from 20 Hz to beyond 500 MHz. Very few other measuring instruments provide this range in a single sensor/meter. In addition to the 410B or C, you will also need a probe adapter HP model #11042A.

Do not take the probe apart for inspection because that can change the calibration. You can quickly check the probe by feeling it after it has been warmed up for about 15 minutes. If the body of it feels warm it is probably working. Inside, the 410B is quite different from the C model, with the B being simpler. The meter scales are also different; the 410C offers better resolution and perhaps better accuracy.

To make RF power measurements, remove the ac probe tip and twist lock the probe into the 11042A probe adapter. Attach the output of the adapter to a dummy load and use the formula

$$P = \frac{E^2}{R} \quad (8)$$

where

P = power, in watts

E = value given by the meter, in volts

R = resistance of the dummy load, in ohms.

The resistance of the dummy load should be accurately known to at least  $\pm 0.1 \Omega$ , preferably measured with a four-

wire arrangement as described in the section on ohmmeters. For frequent measurements, make a chart of voltage vs power at your most often used wattages.

### The Bird Calorimetric Power Meter

The Bird Electronic Corporation produces a line of laboratory-grade calorimetric RF power meters. They contain a water and glycol mixture in a closed circuit piping arrangement not unlike that in an air conditioner or refrigerator. A pump forces the coolant through a heat exchanger and then to a chamber containing a load resistor. This resistor is heated by the power source under measurement.

Temperature sensors at the input and the output of the chamber measure the heat rise, which is proportional to the power delivered to the resistor. This heat rise is displayed by either analog or digital displays.

Occasionally available as industrial surplus, the HP434 is a long standing industry standard calorimetric meter. It is calibrated by a very accurate internal dc voltage. The input load has a flat fre-

quency response from dc to 12.5 GHz and it can measure power from below 1 mW to 10 W. It also uses a resistor in the flow of a special oil as a load. The oil transfers heat from the dummy load to another resistor that is one arm of a bridge circuit. As the value of this sensing resistor changes from the heat, it forces the bridge out of balance. The bridge meter is calibrated to represent power at the input dummy load.

In practice, the plumbing and metal work needed to accomplish this is very complicated. Don't attempt repairs. Even so "the box," as it is called, can be sent back to the factory for repair. The oil is Dow Corning 200, which is only slightly thicker than alcohol and evaporates quickly. If you get an instrument of this caliber in working condition, however, it can be a powerful tool to measure RF power accurately over a wide range of frequency and power.

### DIRECTIONAL WATTMETERS

Directional wattmeters of varying quality are commonly used by the amateur community. The high quality standard is made by the Bird Electronic Corporation, who call their proprietary line **THRULINE**. The units are based on a sampling system built into a short piece of 50- $\Omega$  transmission line with plug-in elements for various power and frequency ranges.

### AC BRIDGES

In its simplest form, the ac bridge is exactly the same as the Wheatstone bridge discussed earlier in the dc measurement section of this chapter. However, complex

impedances can be substituted for resistances, as suggested by **Fig 26.14A**. The same bridge equation holds if  $Z$  (complex impedance) is substituted for  $R$  in each arm. For the equation to be true, however, both phase angles and magnitudes of the impedances must balance; otherwise, a true null voltage is impossible to obtain. This means that a bridge with all "pure" arms (pure resistance or reactance) cannot measure complex impedances; a combination of  $R$  and  $X$  must be present in at least one arm aside from the unknown.

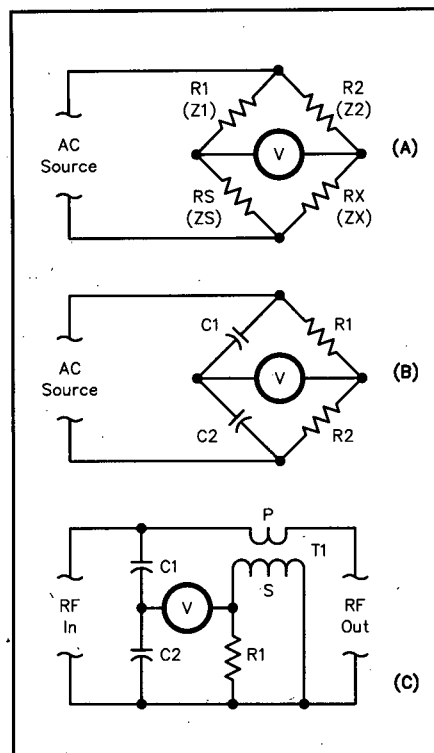

The actual circuits of ac bridges take many forms, depending on the intended measurement and the frequency range to be covered. As the frequency increases, stray effects (unwanted capacitances and inductances) become more pronounced. At RF, it takes special attention to minimize them.

Most amateur built bridges are used for RF measurements, especially SWR measurements on transmission lines. The circuits at **Fig 26.14B** and **C** are favorites for this purpose.

**Fig 26.14B** is useful for measuring both transmission lines and lumped constant components. Combinations of resistance and capacitance are often used in one or more arms; this may be required for eliminating the effects of stray capacitance. The bridge shown in **Fig 26.14C** is used only on transmission lines and only on those lines having the characteristic impedance for which the bridge is designed.

### SWR Measurement

The theory behind SWR measurement

**Fig 26.14** — **A** shows a bridge circuit generalized for ac or dc use. **B** is a form of ac bridge for RF applications. **C** is an SWR bridge for use in transmission lines.

is covered in the **Transmission Lines** chapter and more fully in *The ARRL Antenna Book*. Projects to measure SWR appear in the **Station Accessories** chapter of this *Handbook*.

## Frequency Measurement

The FCC Rules for Amateur Radio require that transmitted signals stay inside the frequency limits of bands consistent with the operator's license privileges. The exact frequency need not be known, as long as it is within the limits. On these limits there are no tolerances: Individual amateurs must be sure that their signal stays safely inside. The current limits for each license class can be found in the **References** chapter and in the current edition of *The FCC Rule Book*, published by the ARRL.

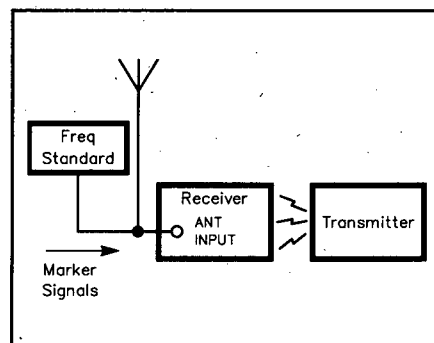

Staying within these limits is not difficult; many modern transceivers do so automatically, within limits. If your radio uses a PLL synthesized frequency source,

just tune in WWV or another frequency standard occasionally.

Checks on older equipment require some simple equipment and careful adjusting. The equipment commonly used is the frequency marker generator and the method involves use of the station receiver, as shown in **Fig 26.15**.

### FREQUENCY MARKER GENERATORS

A marker generator, in its simplest form, is a high-stability oscillator that generates a series of harmonic signals. When an appropriate fundamental is chosen, harmonics fall near the edges of the amateur frequency allocations.

**Fig 26.15** — A setup for checking transmitter frequency. Use care to ensure that the transmitter does not overload the receiver. False signals would result; see text.

Most US amateur band and subband limits are exact multiples of 25 kHz. A 25-kHz fundamental frequency will therefore produce the right marker signals if its harmonics are strong enough. But since harmonics appear at 25-kHz intervals throughout the spectrum, there is still a problem of identifying particular markers. This is easily solved if the receiver has reasonably good calibration. If not, most marker circuits provide a choice of fundamental outputs, say 100 and 50 kHz as well as 25 kHz. Then the receiver can be first set to a 100-kHz interval. From there, the desired 25-kHz (or 50-kHz) points can be counted. Greater frequency intervals are rarely required. Instead, tune in a signal from a station of known frequency and count off the 100-kHz points from there.

### **Transmitter Checking**

To check transmitter frequency, tune in the transmitter signal on a calibrated receiver and note the dial setting at which it is heard. To start, reduce the transmitter to its lowest possible level to avoid receiver overload. Also, place a direct short across the receiver antenna terminals, reduce the RF gain to minimum and switch in any available receiver attenuators to help prevent receiver IMD, overload and possible false readings.

Place the transmitter on standby (not transmitting) and use the marker generator as a signal source. Tune in and identify the nearest marker frequencies above and below the transmitter signal. The transmitter frequency is between these two known frequencies. If the marker frequencies are accurate, this is all you need to know, except that the transmitter frequency must not be so close to a band (or subband) edge that sidebands extend past the edge.

If the transmitter signal is inside a

marker at the edge of an assignment, to the extent that there is an audible beat note with the receiver BFO turned off, normal CW sidebands are safely inside the edge. (So long as there are no abnormal sidebands such as those caused by clicks and chirps.) For 'phone the safety allowance is usually taken to be about 3 kHz, the usual width of one sideband. A frequency difference of this much can be estimated by noting the receiver dial settings for the two 25-kHz markers that are either side of the signal and dividing 25 by the number of dial divisions between them. This will give the number of kilohertz per dial division. It is a prudent practice to allow an extra kHz margin when setting the transmitter close to a band or subband edge (5-kHz is a safe HF margin for most modes on modern transmitters).

### **Transceivers**

The method described above is good when the receiver and transmitter are separate pieces of equipment. When a transceiver is used and the transmitting frequency is automatically the same as that to which the receiver is tuned, setting the tuning dial to a spot between two known marker frequencies is all that is required. The receiver incremental tuning control (RIT) must be turned off.

The proper dial settings for the markers are those at which, with the BFO on, the signal is tuned to zero beat (the spot where the beat note disappears as tuning makes its pitch progressively lower). Exact zero beat can be determined by a very slow rise and fall of background noise, caused by a beat of a cycle or less per second. In receivers with high selectivity it may not be possible to detect an exact zero beat, because low audio frequencies from beat notes may be prevented from reaching the

speaker or headphones.

Most commercial equipment has some way to match either the equipment's internal oscillator or marker generator with the signal received from WWV on one of its short-wave frequencies. It is a good idea to do this check on a new piece of gear. A recheck about a month later will show if anything has changed. Normal commercial equipment drifts less than 1 kHz after warm up.

Also check the dial linearity of equipment that has an analog dial or subdial. Often analog dials do not track frequency accurately across an entire band. Such radios usually provide for pointer adjustment so that dial error can be minimized at the most often used part of a band.

### **Frequency-Marker Circuits**

The frequency in most amateur frequency markers is determined by a 100-kHz or 1-MHz crystal. Although the marker generator should produce harmonics every 25-kHz and 50-kHz, crystals (or other high-stability resonators) for frequencies lower than 100 kHz are expensive and rare. There is really no need for them, however, since it is easy to divide the basic frequency down to the desired frequency; 50- and 25-kHz steps require only two successive divisions by two (from 100 kHz). In the division process, the harmonics of the generator are strengthened so they are useful up to the VHF range. Even so, as frequency increases the harmonics weaken.

Current marker generators are based on readily available crystals. A 1 MHz basic oscillator would first be divided by 10 to produce 100 kHz and then followed by two successive divide-by-two stages to produce 50 kHz and 25 kHz.

## **A MARKER GENERATOR WITH SELECTABLE OUTPUT**

Fig 26.16 shows a marker generator with selectable output for 100, 50 or 25-kHz intervals. It provides marker signals well up into the 2-m band. The project was first built by Bruce Hale, KB1MW, in the ARRL Lab. A more detailed presentation appeared in the **Station Accessories** chapter of *Handbooks* from 1987 through 1994. An etching pattern and parts-placement diagram are available for this project.

Write, phone or e-mail the Technical Department Secretary at ARRL HQ and request the '95 *Handbook* Marker Generator package.

A 1, 2 or 4-MHz computer-surplus crystal is suitable for Y1. Several prototypes were built with such crystals and all could be tuned within 50 Hz at 100 kHz. The marker division ratio must be chosen once the crystal frequency is selected. This is accomplished by means of several jump-

ers that disable part or all of U2A, the dual flip-flop IC. When Y1 is a 1-MHz crystal, U2 may be omitted entirely. **Table 26.2** gives the jumper placement for each crystal frequency.

The prototypes were built with TTL logic ICs. Unused TTL gate inputs should always be connected either to ground or to VCC through a pull-up resistor. If low-power Schottky (they have "LS" as part of their numerical designator) parts are avail-

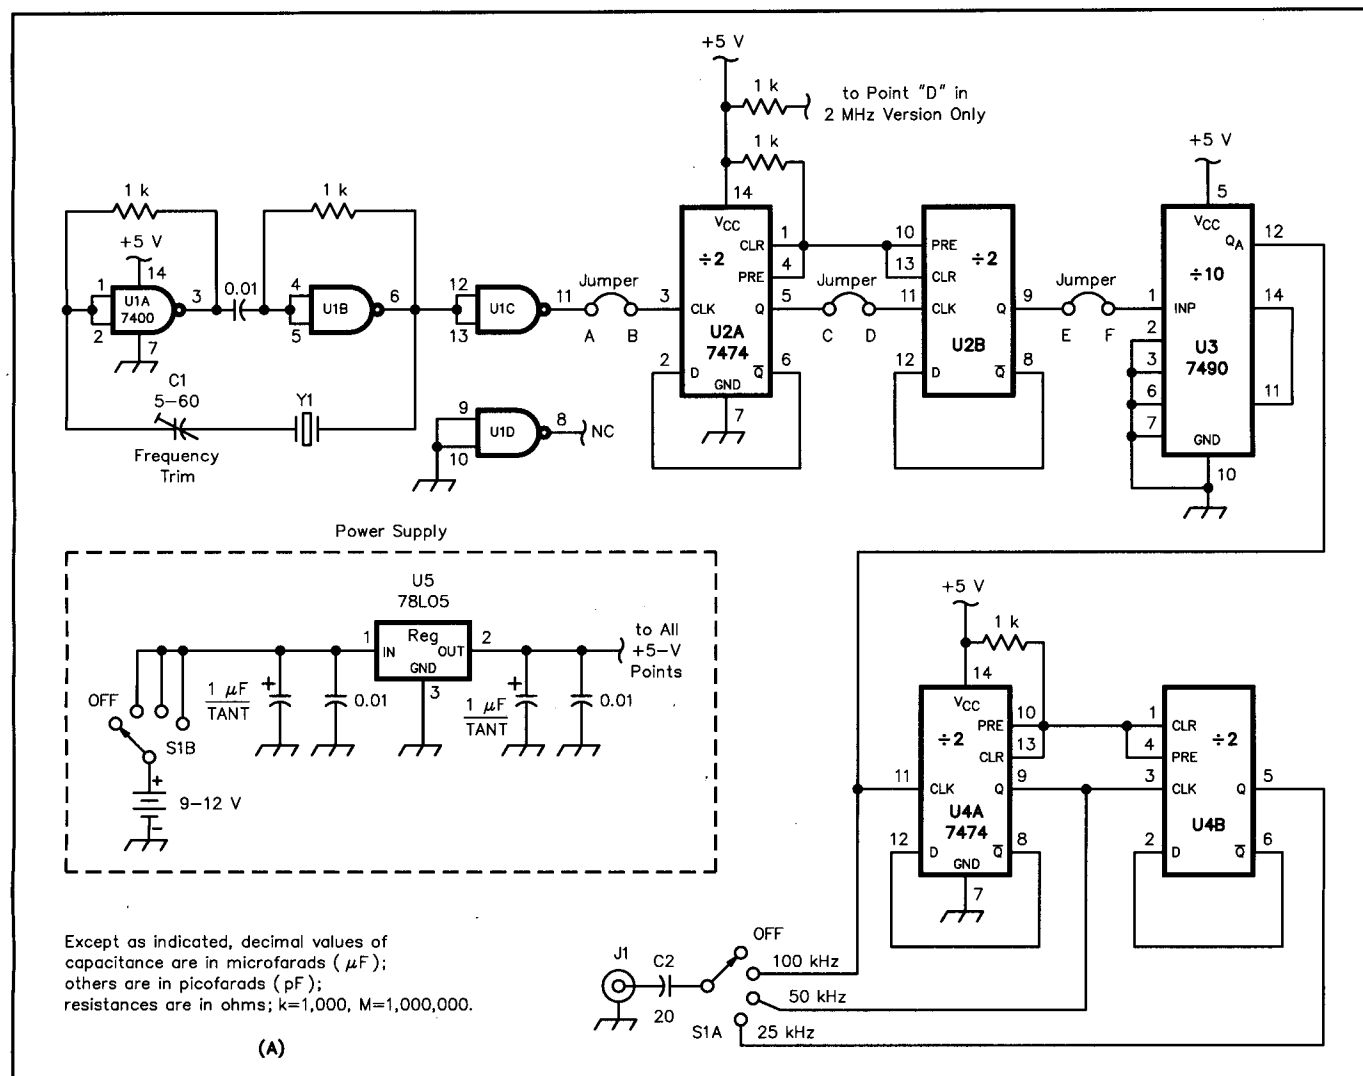

able for U1 through U4, use them. They draw much less current than plain TTL, and will greatly extend battery life.

**Table 26.2**

**Marker Generator Jumper Placement**

Crystal Frequency	Jumper Placement
1 MHz	A to F (U2 not used)
2 MHz	A to B C to F D to +5 V, via 1-k $\Omega$ resistor
4 MHz	A to B C to D E to F

**Fig 26.16 — Schematic diagram and photo of the marker generator.**

C1 — 5-60 pF miniature trimmer capacitor.  
C2 — 20-pF disc ceramic.  
U1 — 7400 or 74LS00 quad NAND gate.

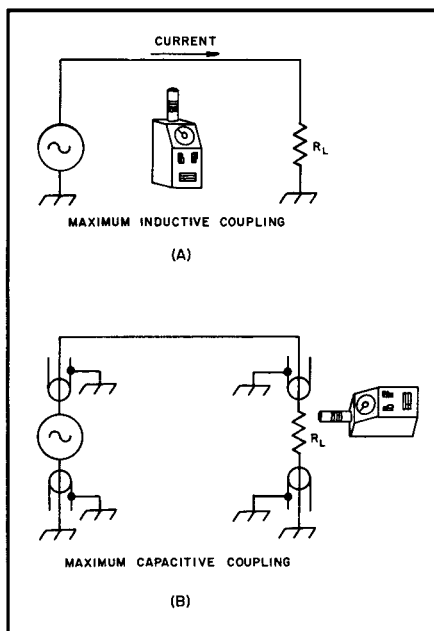

U2, U4 — 7474 or 74LS74 dual D flip-flop.  
U3 — 7490 or 74LS90 decade counter.

U5 — 78L05, 7805 or LM340-T5 5-V voltage regulator.  
Y1 — 1, 2 or 4-MHz crystal in HC-25, HC-33 or HC-6 holder.

## DIP METERS

This device is often called a transistor dip meter or a grid-dip oscillator (from vacuum-tube days). Most dip meters can also serve as absorption frequency meters (in this mode measurements are read at the current peak, rather than the dip). Further, some dip meters have a connection for headphones. The operator can usually hear signals that do not register on the meter. Because the dip meter is an oscillator, it can be used as a signal generator in certain cases where high accuracy or stability are not required.

A dip meter may be coupled to a circuit

**Fig 26.17 — Dip meter coupling. (A) uses inductive coupling and (B) uses capacitive coupling.**

either inductively or capacitively. Inductive coupling results from the magnetic field generated by current flow. Therefore, inductive coupling should be used when a conductor with relatively high current is convenient. Maximum inductive coupling results when the axis of the pick-up coil is placed perpendicular to a nearby current path (see Fig 26.17).

Capacitive coupling is required when current paths are magnetically confined or shielded. (Toroidal inductors and coaxial cables are common examples of magnetic self shielding.) Capacitive coupling depends on the electric field produced by voltage. Use capacitive coupling when a point of relatively high voltage is convenient. (An example might be the output of a 12-V powered RF amplifier. *Do not* attempt dip-meter measurements on true high-voltage equipment such as vacuum-tube amplifiers or switching power supplies while they are energized.) Capacitive coupling is maximum when the end of the pick-up coil is near a point of high voltage (see Fig 26.17). In either case, the circuit under test is affected by the presence of the dip meter. Always use the minimum coupling that yields a noticeable indication.

Use the following procedure to make reliable measurements. First, bring the dip meter gradually closer to the circuit while slowly varying the dip-meter frequency. When a current dip occurs, hold the meter steady and tune for minimum current. Once the dip is found, move the meter away from the circuit and confirm that the dip comes from the circuit under test (the current reading should increase with distance from the circuit until the dip is gone). Finally, move the meter back toward the circuit until the dip is just noticed. Retune the meter for minimum current and read

the dip-meter frequency with a calibrated receiver or frequency meter.

The current dip of a good measurement is smooth and symmetrical. A asymmetrical dip indicates that the dip-meter oscillator frequency is being significantly influenced by the test circuit. Such conditions do not yield usable readings.

A measurement of effective unloaded inductor  $Q$  can be made with a dip meter and an RF voltmeter (or a dc voltmeter with an RF probe). Make a parallel resonant circuit using the inductor and a capacitance equal to that of the application circuit. Connect the RF voltmeter across this parallel combination and measure the resonant frequency. Adjust the dip-meter/circuit coupling for a convenient reading on the voltmeter, then maintain this dip-meter/circuit relationship for the remainder of the test. Vary the dip meter frequency until the voltmeter reading drops to 0.707 times that at resonance. Note the frequency of the dip meter and repeat the process, this time varying the frequency on the opposite side of resonance. The difference between the two dip meter readings is the test-circuit bandwidth. This can be used to calculate the circuit  $Q$ :

$$Q = \frac{f_0}{BW} \quad (9)$$

where

$f_0$  = operating frequency,

BW = measured bandwidth in the same units as the operating frequency.

When purchasing a dip meter, look for one that is mechanically and electrically stable. The coils should be in good condition. A headphone connection is helpful. Battery-operated models are convenient for antenna measurements.

## A DIP METER WITH DIGITAL DISPLAY

An up to date dip meter was described by Larry Cicchinelli in the October 1993 issue of *QEX*. It consists of a dip meter with a three-digit frequency display. The analog portion of the circuit consists of an FET oscillator, voltage-doubler detector, dc-offset circuit and amplifier. The digital portion of the circuit consists of a high-impedance buffer, prescaler, counter, display driver, LED display and control circuit.

### Circuit Description

The dip meter shown in Fig 26.18 has four distinct functional blocks. The RF os-

cillator is a standard Colpitts using a common junction FET, Q1, as the active element. Its range is about 1.7 to 45 MHz. The 200-pF tuning capacitor gives a 2:1 tuning range. A 2:1 frequency range requires a capacitor with a 4:1 range. The sum of the minimum capacitance of the variable, the capacitors across the inductor and the strays must therefore be in the order of 70 pF. The values of L1 were determined experimentally by winding the coils and observing the lower and upper frequency values. [Table 26.3 shows winding data calculated from the author's schematic.—Ed.]

**Fig 26.18 — A schematic diagram of the dip meter. All diodes are 1N914 or similar. All resistors are 1/4 W, 5%.**

Q1, Q2 — MPF102 JFET transistor.

Q3, Q6, Q7, Q8 — 2N3906 PNP transistor.

Q4, Q5, Q9, Q10 — 2N3563 (or any general purpose NPN).

U1 — LM324.

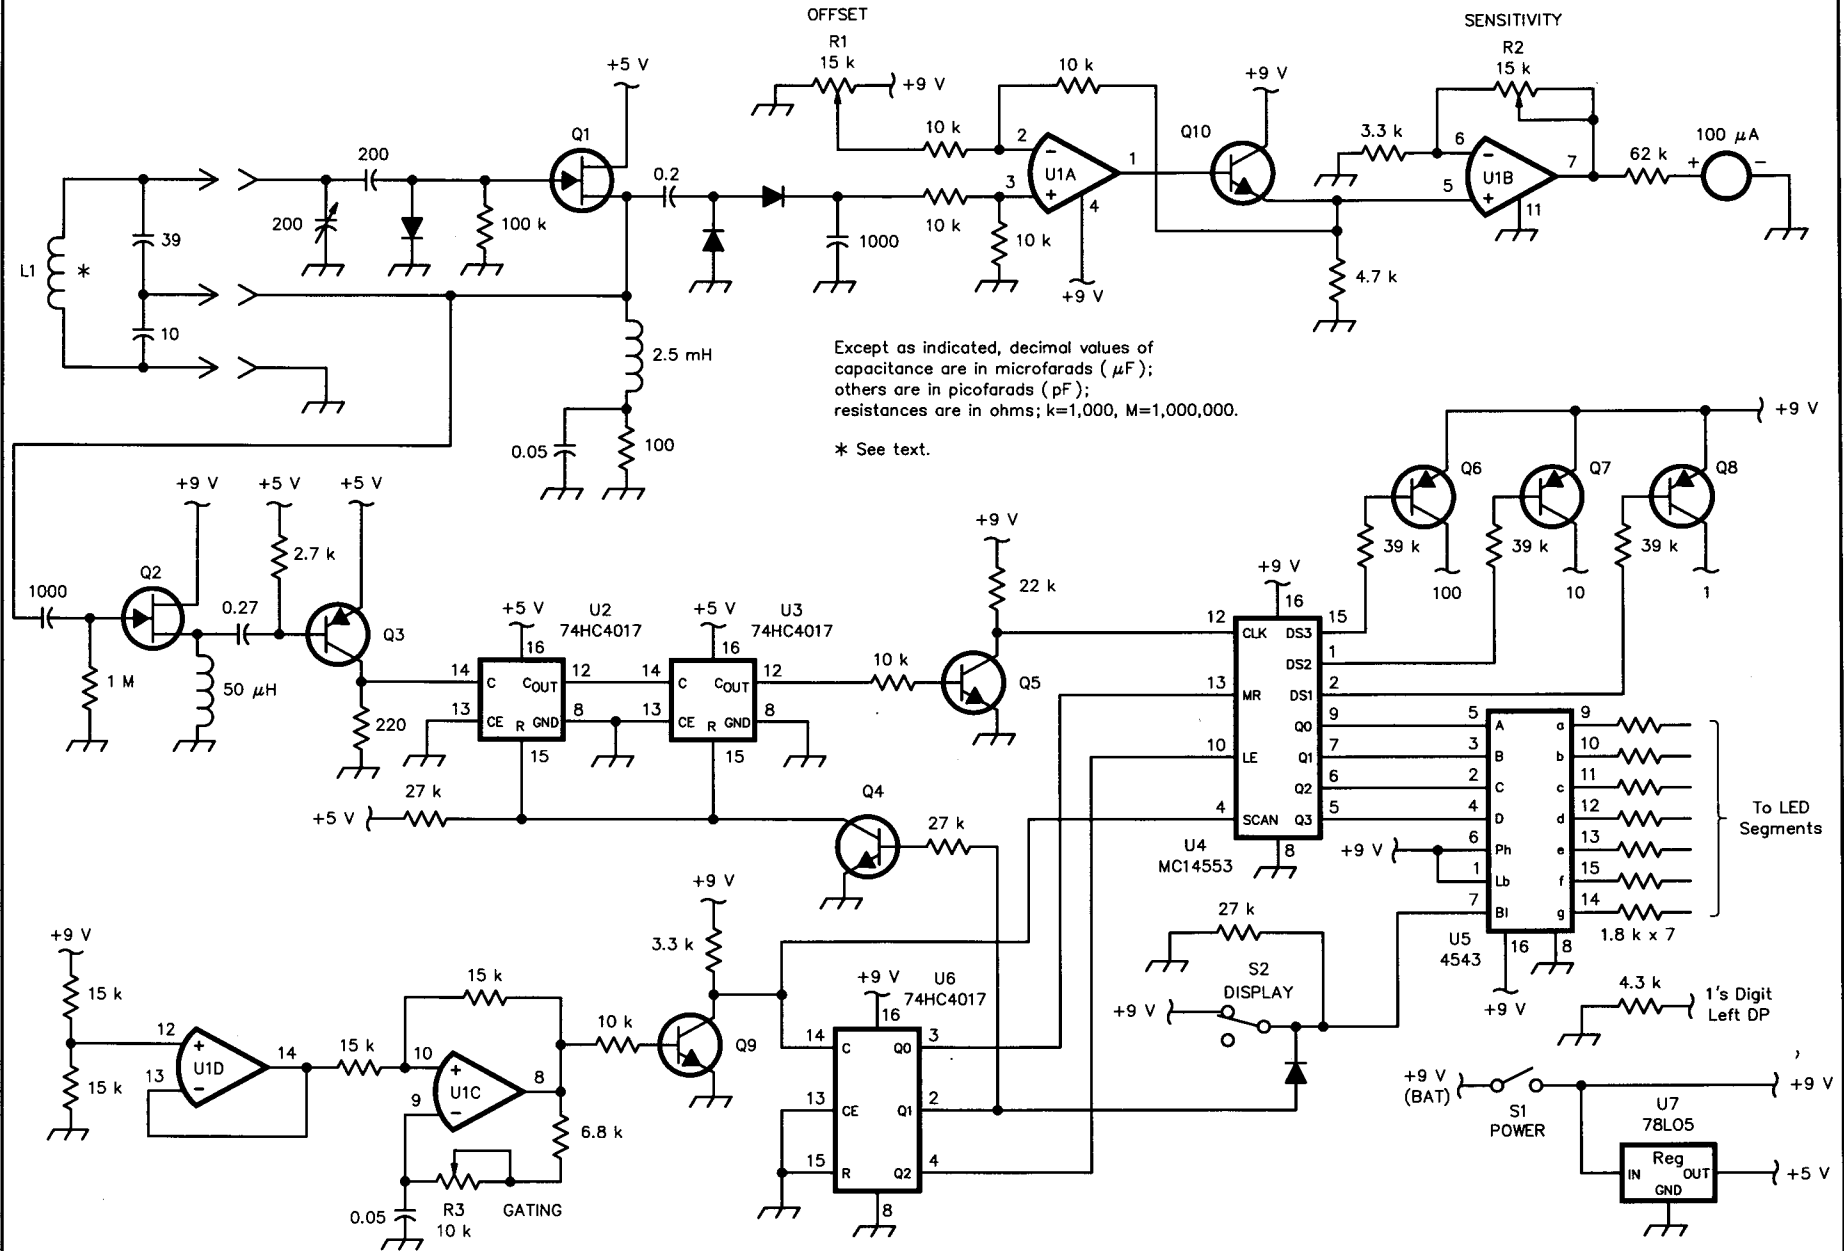

U2, U3 — 74HC4017.

U4 — MC14553.

U5 — 4543.

U6 — 4017.

U7 — 78L05.

**Table 26.3**  
**Calculated Coil Data for the Dip Meter**

Frequency (MHz)	L $\mu$ H	Turns
1.7 to 3.1	48.6	52
2.8 to 5.9	16.3	23
5.6 to 11.9	4.0	9
9.7 to 20.7	1.3	5
19.0 to 45.0	0.3	2

The coil sizes were experimentally determined, and the coils are constructed on 1/4-inch-diameter plug-in coil forms with #20 enameled wire. They are close wound. The number of turns shown are only a starting point; you may need to change them slightly in order to cover the desired frequency range.

The tapped capacitors are mounted inside the coil forms so that their values could be different for each band if required. The frequency spread of the lowest band is less than 2:1 because the tapped capacitor values are larger than those for the other bands. The frequency spread of the highest band is greater than 2:1 because its capacitors are smaller.

The analog display circuit begins with a voltage-doubler detector in order to get higher sensitivity. It drives a dc-offset circuit, U1A. R1 inserts a variable offset that is subtracted from the detector voltage. This allows the variable gain stage, U1B, to be more sensitive to variations in the detector output voltage. Q9 follows U1C to get an output gating voltage closer to ground. The resistor in series with the meter is chosen to limit the meter current to a safe value. For example, if a 1-mA meter is used, the resistor should be 8.2 k $\Omega$ .

The prescaler begins with a high-impedance buffer and amplifier, Q2 and Q3. If you are going to use the meter for the entire frequency range described, take care in the layout of both the oscillator and buffer/amplifier circuits. The digital portion of the

prescaler is a divide-by-100 circuit consisting of two divide-by-10 devices, U2 and U3. The devices used were selected because they were available. Any similar devices may be used as long as the reset circuit is compatible. Q5 is a level translator that shifts the 5-V signal to 9 V.

The first part of the digital display block is the oscillator circuit of U1C, which creates the gate time for the frequency counter. R3 adjusts the oscillator to a frequency of 500 Hz, yielding a 1-ms gate. The best way to set this frequency is to listen for the dip-meter output on a communications receiver and adjust R3 until the display agrees with the receiver. Once this calibration has been made for one of the bands, all the bands are calibrated. U1D gives a low-impedance voltage reference for U1C. Q9 was added to the output of the oscillator to remove a small glitch, which can cause the counter to trigger incorrectly. This type of oscillator has the advantage of simplicity. This circuit is fairly stable, easy to adjust and has a low parts count.

The digital system controller, U6, is a divide-by-10 counter. It has 10 decoded outputs, each of which goes high for one period of the input clock. The Q0 output is used to reset the frequency counter, U4. The Q1 output is used to enable the prescaler and disable the display and the Q2 output latches the count value into the frequency counter. Since the prescaler can only count while Q1 is high, it will be enabled for only 1 ms. Normally a 1-ms gate will yield 1-kHz resolution. Since the circuit uses a divide-by-100 prescaler, the resolution becomes 100 kHz.

The frequency counter, U4, is a three-digit counter with multiplexed BCD outputs. The clock input is driven from the prescaler, hence it is the RF oscillator frequency divided by 100. This signal is present for only 1 ms out of every 10 ms. The digit scanning is controlled by the 500-Hz oscillator of U1C.

U5 is a BCD-to-seven-segment decoder/driver. Its outputs are connected to each of the three common-anode, seven-segment

displays in parallel. Only the currently active digit will be turned on by the digit strobe outputs of U5, via Q6, Q7 and Q8. The diode connected to the blanking input of U5 disables the display while U4 is counting. U7 is a 5-V regulator that allows the use of a single 9-V battery for both the circuit and the LEDs. S2 turns on the displays once the unit has been adjusted for a dip.

The circuit draws about 20 mA with the LEDs off and up to 35 mA with the LEDs on.

Many of the resistor values are not critical, and those used were chosen based upon availability; the op-amp circuits depend primarily on resistance ratios. The resistor at the collector of Q3 is critical and should not be varied. Use 0.27- $\mu$ F monolithic capacitors. They have the required good high-frequency characteristics over the range of the meter.

Most of the parts can be purchased from Digi-Key. They did not have the '4543 IC, which was purchased from Hosfelt Electronics. (See Address List in the **References** chapter). The 74HC4017 may be substituted with a 74HCT4017. The circuit is built on a 4-inch-square perf board (with places for up to 12 ICs) and is housed in a 7 $\times$ 5 $\times$ 3-inch minibox.

### Operation

To use the unit, set the gain, R2, fully clockwise for maximum sensitivity. With this setting, the output of the offset circuit (Q10 emitter) is at ground. As R1 is rotated, the voltage on the arm approaches and then becomes less than, the detector output. At this point the meter will start to deflect upward. Adjust R1 so that the meter reads about center scale. (Manual adjustment allows for variations in the output level of the RF oscillator.) As L1 is brought closer to the circuit under test, the meter will deflect downward as energy is absorbed by the circuit. For best results use the minimum possible coupling to the circuit being tested. If the dip meter is overcoupled to the test circuit, the oscillator frequency will be pulled.

## FREQUENCY COUNTERS

One of the most accurate means of measuring frequency is a frequency counter. This instrument is capable of numerically displaying the frequency of the signal supplied to its input. For example, if an oscillator operating at 8.244 MHz is connected to a counter input, 8.244 would be displayed. At present, counters are usable well up into the gigahertz range. Most counters that are used at high frequencies make use of a prescaler ahead of a basic low-frequency counter. A prescaler divides the high-frequency signal by 10, 100, 1000 or some other fixed amount so that a low-frequency counter can display the operating frequency.

The accuracy of the counter depends on its

internal crystal reference. A more accurate crystal reference yields more accurate readings. Crystals for frequency counters are manufactured to close tolerances. Most counters have a trimmer capacitor so that the crystal can be set exactly on frequency. Crystal frequencies of 1 MHz, 5 MHz or 10 MHz have become more or less standard. For calibration, harmonics of the crystal can be compared to a known reference station, such as those shown in Table 26.1, or other frequency standard and adjusted for zero beat.

Many frequency counters offer options to increase the accuracy of the counter timebase; this directly increases the counter accuracy. These options usually

employ temperature-compensated crystal oscillators (TCXOs) or crystals mounted in constant temperature ovens that keep the crystal from being affected by changes in ambient (room) temperature. Counters with these options may be accurate to 0.1 ppm (part per million) or better. For example, a counter with a timebase accuracy of 5.0 ppm and a second counter with a TCXO accurate to 0.1 ppm are available to check a 436-MHz CW transmitter for satellite use. The counter with the 5-ppm timebase could have a frequency error of as much as 2.18 kHz, while the possible error of the counter with the 0.1 ppm timebase is only 0.0436 kHz.

## Other Instruments and Measurements

This section covers a variety of test equipment that is useful in receiver and transmitter testing. It includes RF and audio generators, an inductance meter, oscilloscopes, spectrum analyzers, a calibrated noise source, a noise bridge, an advanced resonance indicator, combiners, attenuators and dummy loads. A number of applications of this equipment to basic transmitter and receiver testing is also included.

### RF OSCILLATORS FOR CIRCUIT ALIGNMENT

Receiver testing and alignment uses equipment common to ordinary radio service work. Inexpensive RF signal generators are available, both complete and in kit form. However, any source of signal that is weak enough to avoid overloading the receiver usually will serve for alignment work. The frequency marker generator is a satisfactory signal source. In addition, its frequencies, although not continuously adjustable, are known far more precisely, since the usual signal-generator calibration is not highly accurate. An attenuator described later in this chapter can be added for relative dB measurements. When buying a used or inexpensive signal generator, look for these attributes: output level is calibrated, the output doesn't "ring" too badly when tapped, and doesn't drift too badly when warmed up. Many military surplus units are available that can work quite well. Commercial units such as the HP608 are

big and stable, and they may be inexpensive.

### AUDIO-FREQUENCY OSCILLATORS

An audio signal generator should provide a reasonably pure sine wave. The best oscillator circuits for this use are RC coupled, operating as close to a class-A amplifier as possible. Variable frequencies covering the entire audio range are needed for determining frequency response of audio amplifiers.

An oscillator generating one or two frequencies with good waveform is sufficient for most phone-transmitter testing and simple troubleshooting in AF amplifiers. A two-tone (dual) oscillator is very useful for testing and adjusting sideband transmitters.

A circuit of a simple RC oscillator that is useful for general testing is given in **Fig 26.19**. This Twin-T arrangement gives a waveform that is satisfactory for most purposes. The oscillator can be operated at any frequency in the audio range by varying the component values. R1, R2 and C1 form a low-pass network, while C2, C3 and R3 form a high-pass network. As the phase shifts are opposite, there is only one frequency at which the total phase shift from collector to base is 180°. Oscillation will occur at this frequency. When C1 is about twice the capacitance of C2 or C3 the best operation results. R3 should have a resistance about 0.1 that of R1 or R2 (C2 = C3 and R1 = R2). Output is taken across C1, where the harmonic distortion is least.

Use a relatively high impedance load — 100 k $\Omega$  or more.

Most small-signal AF transistors can be used for Q1. Either NPN or PNP types are satisfactory if the supply polarity is set correctly. R4, the collector load resistor may be changed a little to adjust the oscillator for best output waveform.

**Fig 26.19** — Values for the twin-T audio oscillator circuit range from 18 k $\Omega$  for R1-R2 and 0.05  $\mu$ F for C1 (750 Hz) to 15 k $\Omega$  and 0.02  $\mu$ F for 1800 Hz. For the same frequency range, R3 and C2-C3 vary from 1800  $\Omega$  and 0.02  $\mu$ F to 1500  $\Omega$  and 0.01  $\mu$ F. R4 is 3300  $\Omega$  and C4, the output coupling capacitor, can be 0.05  $\mu$ F for high-impedance loads.

## A WIDE-RANGE AUDIO OSCILLATOR

A wide-range audio oscillator that will provide a moderate output level can be built from a single 741 operational amplifier (Fig 26.20). Power is supplied by two 9-V batteries from which the circuit draws 4 mA. The frequency range is selectable from 8 Hz to 150 kHz. Distortion is approximately 1%. The output level under a light load (10 k $\Omega$ ) is 4 to 5 V. This can be increased by using higher battery voltages, up to a maximum of plus and minus 18 V, with a corresponding adjustment of  $R_F$ .

Pin connections shown are for the TO-5 case and the eight-pin DIP package. Variable resistor  $R_F$  is trimmed for an output level of about 5% below clipping as seen on an oscilloscope. This should be done for the temperature at which the oscillator will normally operate, as the lamp is sensitive to ambient temperature. This unit was originally described by Shultz in November 1974 *QST*; it was later modified by Neben as reported in June 1983 *QST*.

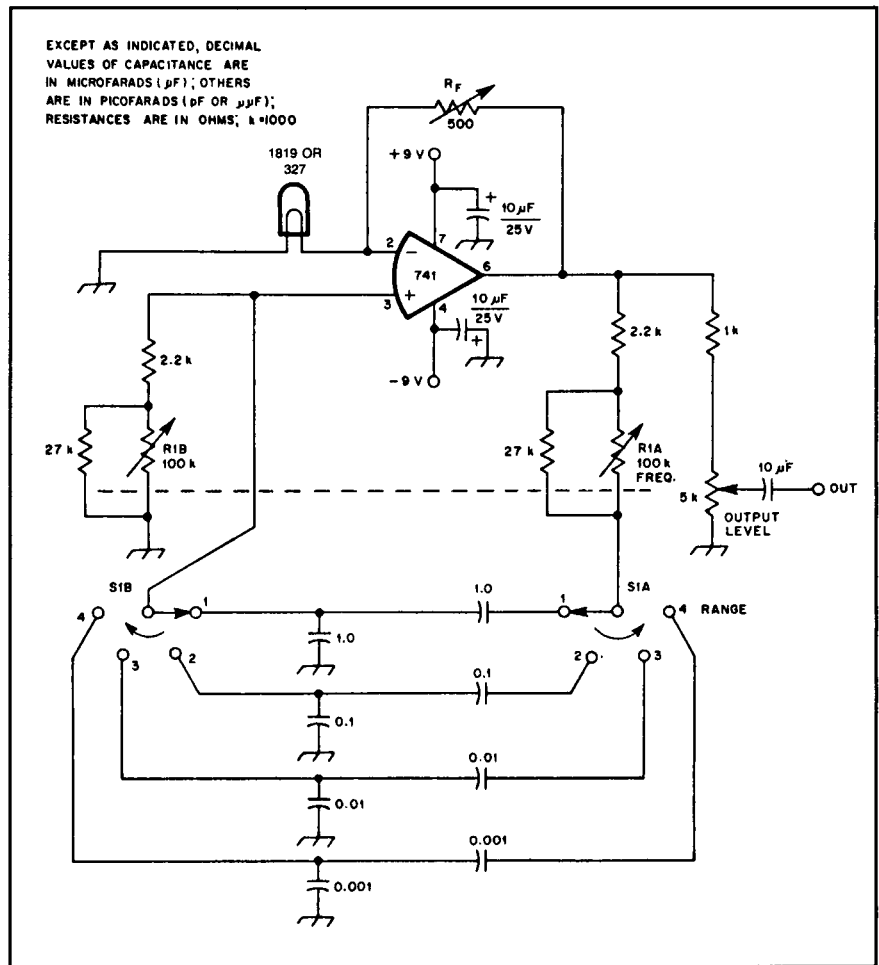

Fig 26.20 — A single IC (741 op amp) based audio oscillator. The frequency range is set by switch S1.

## DUMMY ANTENNAS

A dummy antenna is simply a resistor that can be substituted for an antenna or transmission line for test purposes. The dummy must have the same resistance as the antenna or line it replaces. A 50- $\Omega$  antenna should be replaced with a 50- $\Omega$  dummy load. A dummy antenna permits leisurely transmitter testing without radiating a signal. (Amateur regulations strictly limit the amount of on-the-air testing that may be done.) A dummy antenna is useful in testing receivers because it does not pick up external noise and signals.

For transmitter tests, a dummy antenna must be able to dissipate all of the transmitter output power. For most testing it is important that the dummy act like a perfectly matched transmission line; it should be a pure resistance. This is difficult in

home construction, because nonreactive resistors rated at more than a few watts of safe dissipation are not common. Tubular carborundum nonreactive resistors can often be found in military surplus transmitters and antenna tuners. Such resistors are usually rated from 50 to 100 W. Dummy antennas or dummy loads are available as surplus, and new from manufacturers.

Dummy loads are rated according to power dissipation, duty cycle, and maximum frequency. The traditional "resistor in a paint can" (as sold by the Heath Company for many years) works very well, but some may contain old fashioned transformer oil. Transformer oil may have toxic PCBs in it, whereas mineral oil is not a problem for use around a shack. Check surplus catalogs for surplus loads by Bird,

Micro-match, Sierra, Narda, Weinschel, Hewlett-Packard and others. All are suitable for ham use.

Lab-quality loads are often rated at 1 W or less. In use, large finned power attenuators reduce the test signal to a level appropriate for the load. For example at 30-dB power attenuator (the ARRL Lab's is about 6×12×20 inches) reduces 1500 W to 1.5 W.

Before buying a used dummy load, measure its resistance. Resistances between 50 and 55  $\Omega$  mean it has probably not been overheated, but values such as 45 or 68  $\Omega$  indicate a bad resistor. Most loads are simple to work on. If the parts are available from the manufacturer, a damaged one may be a good choice. A surplus Bird 694 "Termaline" is an excellent 1-kW HF wattmeter and wide-range dummy load.

Stay away from test loads that are not well shielded or that have long leads connecting to other circuits as well as ones with resistors that are obviously too small for the claimed power rating.

An excellent dummy antenna can be made for receiver and low power transmitter testing by installing a 51- or 75- $\Omega$  composition resistor in a PL-259 fitting, as shown in Fig 26.21. Sizes from 0.5 to 2 W are satisfactory. The disc at the end helps reduce lead inductance and completes the shield. Dummy antennas made in this way have good characteristics from dc through the VHF bands. The same technique can be used with BNC and SMA connectors for use up through the UHF bands.

### Increasing Power Ratings

More power can be handled by using a number of 2-W resistors in parallel or series-parallel, but the practice adds some reactance. If the load is for use only on the HF bands this is a practical method for getting increased dissipation in a dummy antenna. Stray inductance is the main problem; it can be minimized by mounting the resistors on flat copper strips or sheets, as shown in Fig 26.22.

Resistors are usually rated for continuous dissipation in free air. In practice, the maximum power dissipated can be in-

**Fig 26.21 — Dummy antenna built into a coax plug. A composition resistor is soldered as shown; the outside cap screws on after soldering.**

creased for short time periods. Thus with keying that has a duty cycle (the ratio of the on time to the period of a complete on-off cycle) of 50%, the rating can be doubled. The duty cycle for SSB is usually taken as 30% or less. The best way of judging is to feel the resistors occasionally (with the power off); if too hot to touch, they may be dissipating too much power. At extreme power levels, however, it doesn't matter how short the time is—small resistors will be damaged.

Years ago, ordinary incandescent light bulbs were used as dummy loads for vacuum tube transmitters. Operators would tune the transmitter for maximum light output. While this is visually satisfying, it's not a good idea: Light bulbs are

**Fig 26.22 — Resistors wired in series-parallel and mounted in the open air increase the power rating of a small dummy antenna. A flat copper bus is used to reduce inductance to a minimum. Eight 100- $\Omega$ , 2-W composition resistors in two groups, each four resistors in parallel, can be connected in series to form a 50- $\Omega$  dummy load.**

not usually 50  $\Omega$ ; they can have large reactances, so they are not matched to most transmitters. In cases where a higher SWR load is acceptable, however, they may prove useful.

## A SIMPLE INDUCTANCE METER

The inductance meter shown in Fig 26.23 measures the relative Q of a coil as well as its inductance. The Q/L meter is based on a design by Doug DeMaw, W1FB; this version was built by Zachary Lau, KH6CP, in the ARRL Lab. Simple LC Hartley oscillators replace the crystal oscillators used in the original design, eliminating the need for low-pass filters and reducing circuit complexity and cost. The accuracy of the meter is approximately  $\pm 10\%$  using the dial layout shown. Greater accuracy can be achieved by calibrating the meter against known high-accuracy standards.

### Circuit Details

The schematic of the Q/L meter is shown in Fig 26.24. A low-level RF signal is generated using an oscillator and an amplifier (Q1 through Q5). This signal is then applied to a tuned circuit consisting of the inductor under test and a cali-

brated capacitor. The voltage across the tuned circuit is measured using Q6 and displayed on M1, a 200  $\mu\text{A}$  meter. When the capacitor is adjusted for resonance at the frequency of the RF signal, the voltage across the tuned circuit is maximized, resulting in a peak indication on the meter.

The crystal oscillators used in the original versions were replaced with Hartley LC oscillators as a cost-cutting measure. While the Hartley oscillators do not have the great stability of crystal oscillators, they are adequate for this application. The output of the LC oscillators is relatively clean and no additional filtering is needed. The potentiometers from source to ground allow control of the power to the buffer amplifier.

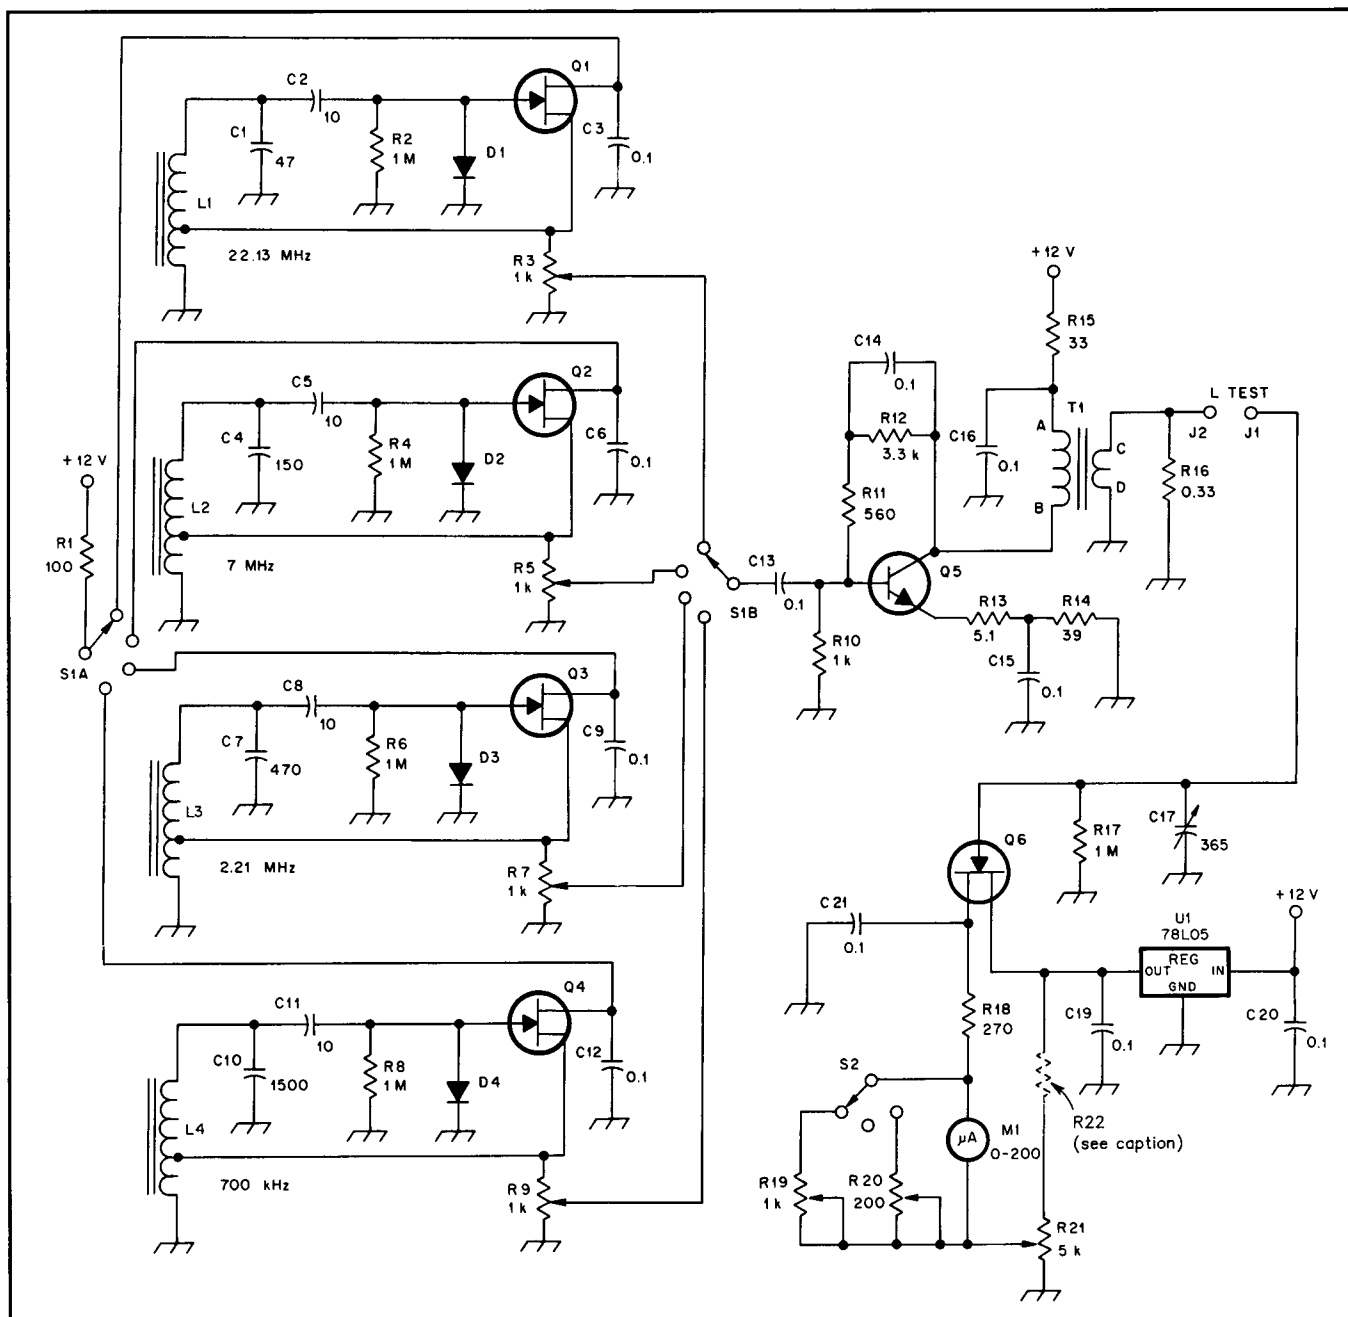

The buffer amplifier is a broadband class-A amplifier with shunt and emitter feedback. T1 is used to match the 0.33- $\Omega$  load to the amplifier, as the load tends

to swamp out the frequency dependence of the circuit.

A voltage-to-current amplifier (Q6) is used to show the amount of RF present at J1.

**Fig 26.23 — The inductance meter is calibrated to provide direct readings of 0.12  $\mu\text{H}$  to 1.8 mH.**

**Fig 26.24 — Inductance meter schematic diagram. All capacitors are disc ceramic unless otherwise noted. All fixed resistors are  $\frac{1}{4}$  or  $\frac{1}{2}$ -W units.**

C1, C2, C4, C5, C7, C8, C10 and C11 — NP0 disc, silver mica or polystyrene.  
 C17 — 365 pF air variable, RADIOKIT BC-01 with Jackson Brothers 4511/DAF vernier or equiv.  
 D1-D4 — High-speed silicon diode; 1N914 or 1N4148.  
 L1 — 17t #26 enameled wire on a T-30-6 core. Tap 5 turns from ground.

L2 — 28t #28 enameled wire on a T-30-2 core. Tap 7 turns from ground.  
 L3 — 47t #28 enameled wire on a T-50-2 core. Tap 12 turns from ground.  
 L4 — 58t #28 enameled wire on a T-50-1 core. Tap 14 turns from ground.  
 M1 — 200- $\mu$ A meter.  
 Q1-Q4, Q6 — 2N5486 or 2N5484 JFET.  
 Q5 — 2N3866 or 2N5109 NPN transistor.

R16 — Three 1- $\Omega$   $\frac{1}{4}$  or  $\frac{1}{2}$ -W resistors in parallel.  
 R22 — Optional resistor (100 to 1000  $\Omega$ ); install if meter moves too quickly.  
 S1 — 2-pole, 4-position rotary switch.  
 S2 — SPDT center-off toggle switch.  
 T1 — 23t #26 enameled wire on an FT-50-43 core with a 1-turn #22 hookup-wire secondary.

For best sensitivity, a small amount of current should always flow through the meter. Two meter shunts are used to select different Q ranges and the 78L05 voltage regulator

supplies Q6 with a constant voltage.

#### Construction

Construction of the Q/L meter is not

tricky. An etching pattern is available from the Technical Department Secretary at ARRL HQ; ask for the '95 *Handbook* LC meter. The toroids must be

wound carefully; the total number of turns on the coils is measured by counting the number of times the wire passes through the hole in the toroid.

The most critical construction detail is the mounting of the capacitor and the terminals for the test inductor. See **Fig 26.25**. The ungrounded capacitor lead is connected to J1 with a piece of #14 wire. The distance from the capacitor to J1 in the version shown here is 2 1/4 inches. The dial layout shown in **Fig 26.26** may be used if this terminal spacing is duplicated. It may be possible to position the capacitor and test inductor closer together and use the given dial layout if a series compensation inductor is used. The accuracy of the dial shown here may be different because of minor differences in construction and components.

The capacitor is mounted three inches from the terminals on an L-shaped mounting bracket below a vernier drive. The 6-to-1 vernier drive is used to prevent the tuning rate from being too fast for high-Q inductors. A piece of plastic scored with a sharp knife is used as a dial pointer. The cabinet used is a Ten-Tec SE-7.

### Testing

An RF probe or oscilloscope should be used to check that the oscillators are working. The peak-to-peak voltage at the input of the buffer amplifier should not exceed 0.40 V to allow the buffer amplifier to operate linearly. The potentiometers in the oscillator circuit, (R3, R5, R7 and R9), are used to adjust the oscillator output levels. They can be adjusted while measuring the oscillator output or simply adjusted for an adequate meter movement while measuring an inductor. If multiple peak readings are noted, the potentiometer is set too high and should be adjusted for less meter deflection. The oscillator output voltage depends somewhat on the FETs used; it may be as low as 0.20 V. R19, the high-Q shunt, should be set for a much lower meter reading than the low-Q shunt, R20.

### Operation

After connecting the unknown inductor

to the test jacks, the sensitivity control is adjusted for a small meter indication of current between 5 and 25  $\mu\text{A}$ . If this is not done, it may be impossible to find a peak, as the detector may be essentially turned off! The low-Q setting is most useful in finding the value of an unknown inductor. The capacitor is then adjusted for a peak meter reading. If no peak can be found, try a different range.

### Limitations

The meter will not be very accurate for inductances below 0.3  $\mu\text{H}$ ; at inductances this low, the measurements are greatly affected by lead length and parts layout. It may be possible to calibrate the unit in terms of Q; the meter is most useful as a measure of relative Q, however. The unit shown here was not calibrated for Q, as the meter reading is affected by the setting of the quiescent point. In addition, Q should always be measured at the frequency of interest, as it has a large change with frequency. The inductance measurements are not absolute; it is not unusual for the inductance of a ferrite-core inductor to vary with frequency. Despite these limitations, this Q/L meter is quite useful in finding approximate inductance values.

**Fig 26.25** — Parts placement within the case of the inductance meter. An L-shaped bracket supports the variable capacitor.

**Fig 26.26** — Dial template for the inductance meter (full size).

## OSCILLOSCOPES

Most engineers and technicians will tell you that the most useful single piece of test and design equipment is the modern triggered sweep oscilloscope (commonly called just a "scope"). Oscilloscopes can measure and display voltage relative to time, showing the waveform pictures usually seen in electronics textbooks. The advances in semiconductor technology have brought the price of a good high-frequency scope within the affordable price range for most hams. The same change in technology has put a large number of older, very good, vacuum-tube oscilloscopes on the surplus market.

Many "boat anchor" (large and heavy) oscilloscopes of lab quality are now available at bargain prices. If one of these used scopes has a good CRT and the built in calibrator shows it to be in relatively good calibration it may give years of further service. Few older scopes have difficulty to find and expensive parts. Older scopes are easier to work on than newer ones, but all have extremely lethal voltages that can "reach out and greet you" if you are not extremely careful. The Tektronics 500 series and 422 portable scopes are traditionally good buys. Some have problems working in high humidity without arcing, however.

Most amateur measurements are at audio or HF, so a 30-MHz dual-trace oscilloscope may be all that is needed. With the wind down of military spending in the 1990s, there have been large numbers of newer scopes available as surplus, such as the Tek 7600 series and USM245 (HP181). These are solid-state models that can be excellent. The NLS (Non-Linear Systems) Miniscope MS-215 portable

scope is quite accurate and very rugged for its size.

**Fig 26.27** shows a simplified diagram of a triggered sweep oscilloscope. At the heart of nearly all scopes is a cathode-ray tube (CRT) display. The CRT allows the visual display of an electronic signal by taking two electric signals and using them to move (deflect) a beam of electrons that strikes the screen. Wherever the beam strikes the phosphorescent screen of the CRT it causes a small spot to glow. The particular location of the spot is a result of the voltage applied to the vertical and horizontal inputs.

All of the other circuits in the scope are used to take the real world signal and convert it to a form usable by the CRT. To trace how a signal travels through the oscilloscope circuitry start by assuming that the trigger select switch is in the INTERNAL position.

The input signal is connected to the input COUPLING switch. The switch allows selection of either the ac part of an ac/dc signal or the total signal. In the ac position, dc is blocked from reaching the vertical amplifier chain (and saturating it; this would cause distortion that would make the displayed ac signals meaningless). It is important to note that it is not advisable to use ac coupling at frequencies below 30 Hz, because the value of the blocking capacitor represents a considerable series impedance to very low-frequency signals.

After the coupling switch, the signal is connected to a calibrated attenuator. This unit is used to reduce the signal to a level that can be tolerated by the scope's vertical amplifier. The vertical amplifier boosts the signal to a level that can drive the CRT

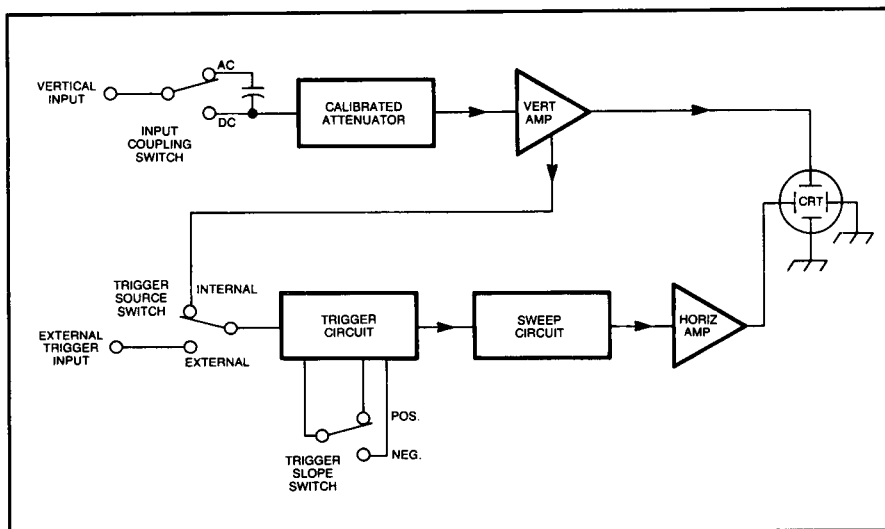

and also adds a bias component to locate the waveform on the screen.

A small sample of the signal from the vertical amplifier is sent to the trigger circuitry. The trigger circuit feeds a start pulse to the sweep generator when the input signal reaches a certain level. The sweep generator gives a precisely timed signal that looks like a triangle (see **Fig 26.28**). This triangular signal causes the scope trace to sweep from left to right, with the zero-voltage point representing the left side of the screen and the maximum voltage representing the right side of the screen.

The sweep circuit feeds the horizontal amplifier that, in turn, drives the CRT. It is also possible to trigger the sweep system from an external source (such as the system clock in a digital system). This is done by using an external input jack with the trigger select switch in the EXTERNAL position.

The trigger system controls the horizontal sweep. It looks at the trigger source (internal or external) to find out if it is positive- or negative-going and to see if the signal has passed a particular level. **Fig 26.29A** shows a typical signal and the dotted line on the figure represents the trigger level. It is important to note that once a trigger circuit is "fired" it cannot fire again until the sweep has moved all the way across the screen from left to right. In normal operation, the TRIGGER LEVEL control is manually adjusted until a stable display is seen. Some scopes have an AUTOMATIC position that chooses a level to lock the display in place without manual adjustment.

**Fig 26.29B** shows what happens when the level has not been properly selected. Because there are two points during a single cycle of the waveform that meet the triggering requirements, the trigger circuit will have a tendency to jump from one trig-

**Fig 26.27** — Typical block diagram of a simple triggered-sweep oscilloscope.

**Fig 26.28** — The sweep trigger starts the ramp waveform that sweeps the CRT electron beam from side to side.

ger point to another. This will make the waveform jitter from left to right. Adjustment of the TRIGGER control will fix this problem.

The horizontal travel of the trace is calibrated in units of time. If the time of one cycle is known, we can calculate the frequency of the waveform. In Fig 26.30, for example, if the SWEEP speed selector is set at  $10\text{ }\mu\text{s/division}$  and we count the number of divisions (vertical bars) between peaks of the waveform (or any similar well defined points that occur once per cycle) we can find the period of one cycle. In this case it is  $80\text{ }\mu\text{s}$ . This means that the frequency of the waveform is  $12,500\text{ Hz}$  ( $1/80\text{ }\mu\text{s}$ ). The accuracy of the measured frequency depends on the accuracy of the scope's sweep oscillator (usually approximately 5%) and the linearity of the ramp generator. This accuracy cannot compete with even the least-expensive frequency counter, but the scope can still be used to determine whether a circuit is functioning properly.

Dual-trace oscilloscopes can display two waveforms at once. This type of scope has two vertical input channels which can be displayed either alone, together or one after the other.

Fig 26.31 shows a simplified block diagram of a dual-trace triggered sweep oscilloscope. The only differences between this scope and the previous example are the additional vertical amplifier and the "channel switching circuit." This block selects whether we display channel A, channel B or both (simultaneously). The dual display is not a true dual display (there is only one electron gun in the CRT) but the dual traces are synthesized in the scope. True dual-trace dual-beam scopes are rare and very expensive.

There are two methods of synthesizing a dual-trace display from a single-beam scope. These two methods are referred to as "chopped mode" and "alternate mode." In the chopped mode a small portion of the channel A waveform is written to the CRT, then a corresponding portion of the channel B waveform is written to the CRT. This procedure is continued until both waveforms are completely written on the CRT. The chopped mode is especially useful where an actual measure of the time difference between the two waveforms is required. The chopped mode is usually most useful on slow sweep speeds (times greater than a few microseconds per division).

In the alternate mode, the complete channel A waveform is written to the CRT followed immediately by the complete channel B waveform. This happens so quickly that it appears that the waveforms are displayed at the same time. This mode of operation is used to measure the abso-

lute phase difference between two signals by triggering both sweeps from the same

vertical input signal. Unfortunately, this mode of operation is not useful at very slow sweep speeds, but is good at most other sweep speeds.

Most dual-trace oscilloscopes also have a feature called "X-Y" operation. This feature allows one channel to drive the horizontal amplifier of the scope (called the X channel) while the other channel (called Y in this mode of operation) drives the vertical amplifier. Some oscilloscopes

Fig 26.29 — In order to produce a stable display the selection of the trigger point is very important. Selecting the trigger point in A produces a stable display, but the trigger shown at B will produce a display that "jitters" from side to side.

Fig 26.30 — Oscilloscopes with a calibrated sweep rate can be used to measure frequency. Here the waveform shown has a period of  $80\text{ }\mu\text{s}$  (8 divisions  $\times 10\text{ }\mu\text{s}$  per division) and therefore a period of  $1/80\text{ }\mu\text{s}$  or  $12.5\text{ kHz}$ .

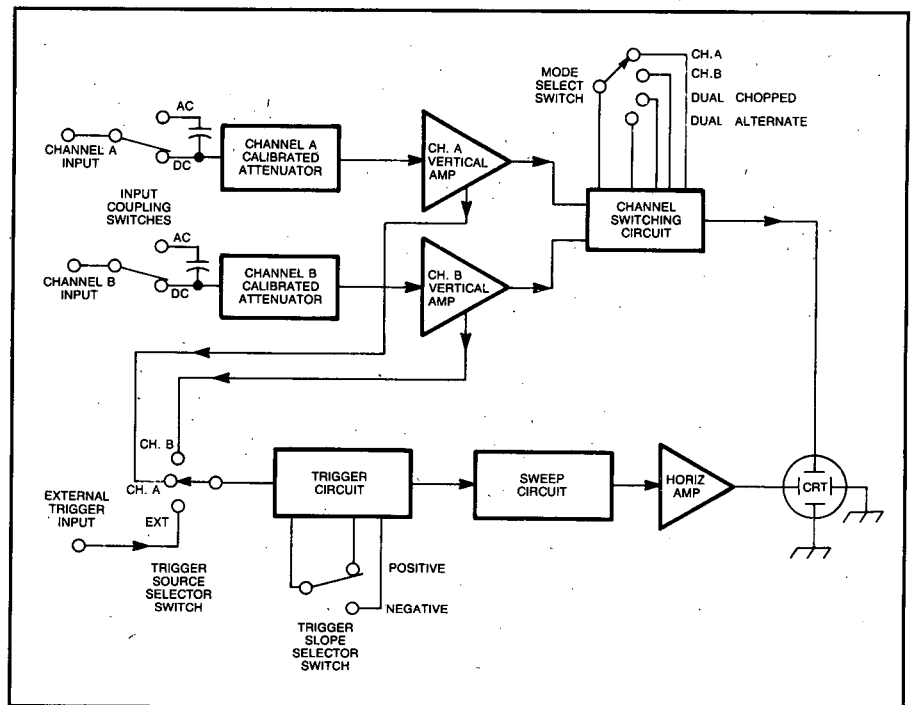

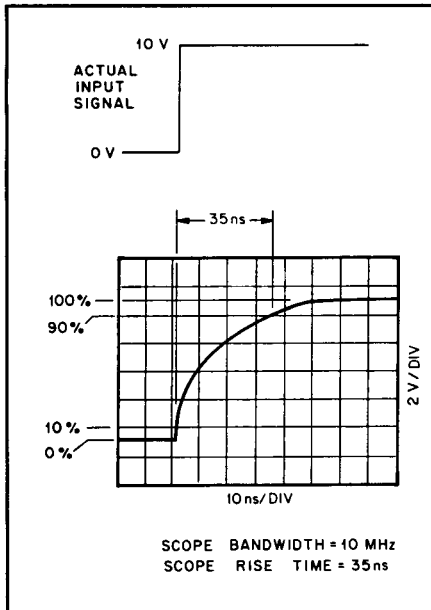

Fig 26.31 — Dual-trace oscilloscope block diagram. Note the two identical input channels and amplifiers.

also have an external Y input. X-Y operation allows the scope to display Lissajous patterns for frequency and phase comparison and to use specialized test adapters such as curve tracers or

**Fig 26.32 — The bandwidth of the oscilloscope vertical channel limits the rise time of the signals displayed on the scope.**

spectrum analyzer front ends. Because of frequency limitations of most scope horizontal amplifiers the X channel is usually limited to a 5- or 10-MHz bandwidth.

Oscilloscopes have limits, primarily in frequency of operation and range of input voltages. For most purposes the voltage range of a scope can be expanded by the use of appropriate probes. The frequency response (also called the bandwidth) of a scope is usually the most important limiting factor. At the specified maximum response frequency, the response will be down 3 dB (0.707 voltage). For example a 100-MHz 1-V sine wave fed into a 100-MHz bandwidth scope will read approximately 0.707 V on the scope display. The same scope at frequencies below 30 MHz (down to dc) should be accurate to about 5%.

A parameter called rise time is directly related to bandwidth. This term describes a scope's ability to accurately display voltages that rise very quickly. For example, a very sharp and square waveform may appear to take some time in order to reach a specified fraction of the input voltage level. The rise time is usually defined as the time required for the display to show a change from the 10% to 90% points of the input waveform, as shown in Fig 26.32. The math-

ematical definition of rise time is given by:

$$t_r = \frac{0.35}{BW} \quad (10)$$

where

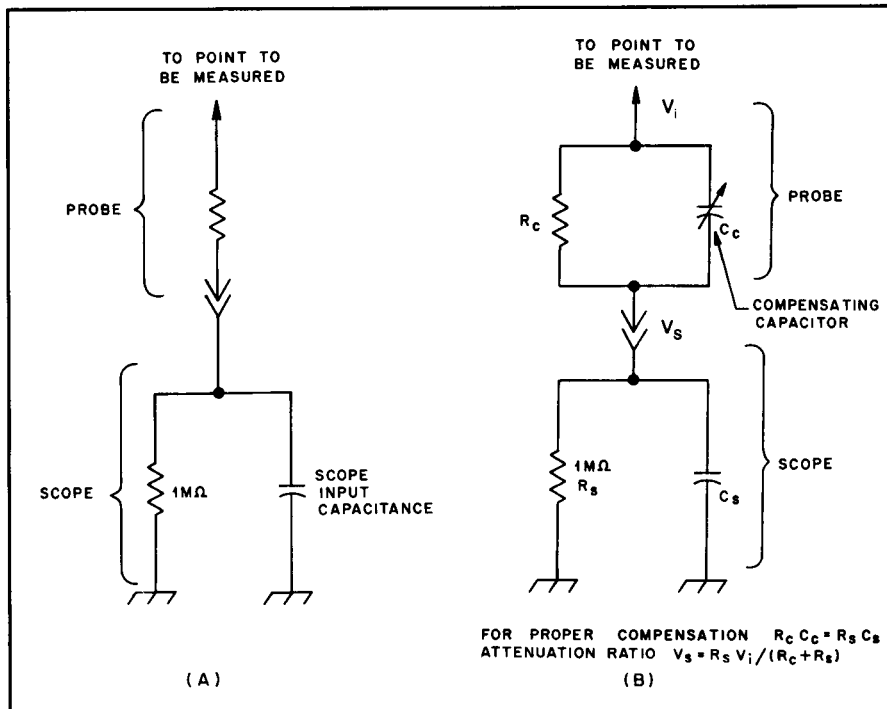

$t_r$  = rise time,  $\mu s$   
BW = bandwidth, MHz.

It is also important to note that all but the most modern (and expensive) scopes are not designed for precise measurement of either time or frequency. At best, they will not have better than 5% accuracy in these applications. This does not change the usefulness of even a moderately priced oscilloscope, however. The most important value of an oscilloscope is that it presents an image of what is going on in a circuit and quickly shows which component or stage is at fault. It can show modulation levels, relative gain between stages and oscillator output.

### Oscilloscope Probes

Oscilloscopes are usually connected to a circuit under test with a short length of shielded cable and a probe. At low frequencies, a piece of small-diameter coax cable and some sort of insulated test probe might do. Unfortunately, at higher frequencies the capacitance of the cable would produce a capacitive reactance much less than the one-megohm input impedance of the oscilloscope. In addition each scope has a certain built-in capacitance at its input terminals (usually between 5 and 35 pF). These two capacitances cause problems when probing an RF circuit with a relatively high impedance.

The simplest method of connecting a signal to a scope is to use a specially designed probe. The most common scope probe is a  $\times 10$  probe (called a "times ten probe"). This probe forms a 10:1 voltage divider using the built-in resistance of the probe and the input resistance of the scope. When using a  $\times 10$  probe, all voltage readings must be multiplied by 10. For example, if the scope is on the 1 V/division range and a  $\times 10$  probe was in use, the signals would be displayed on the scope face at 10 V/division.

**Fig 26.33 — Uncompensated probes such as the one at A are sufficient for low-frequency and slow-rise-time measurements. However, for accurate display of fast rise times with high-frequency components the compensated probe at B must be used. The variable capacitor is adjusted for proper compensation (see text for details).**

**Fig 26.34 — Displays of a square-wave input illustrating undercompensated, properly compensated and overcompensated probes.**

Unfortunately a resistor alone in series with the scope input seriously degrades the scope's rise-time performance and therefore its bandwidth. Since the scope input looks like a parallel, RC circuit the series resistor feeding it causes a significant reduction in available charging current from the source. This may be corrected by using a compensating capacitor in parallel with the series resistor. Thus two dividers are formed: one resistive voltage divider and one capacitive voltage divider. With these two dividers connected in parallel and the RC relationships shown in Fig 26.34, the probe and scope should have a flat response curve through the whole bandwidth of the scope.

To account for manufacturing tolerances in the scope and probe the compensating capacitor is made variable. It is used to "tweak" the probe/scope combination for proper response when they are connected together. Most scopes provide a "calibrator" output that produces a known-frequency square wave for the purpose of adjusting the compensating capacitor in a probe. Fig 26.55 shows possible responses when the probe is connected to the oscilloscope's calibrator jack. The leading edges of the top and bottom traces illustrate an incorrect compensation adjustment. If you get these pictures from the calibrator jack, adjust the compensating capacitor until you get a perfectly square display as is shown in the middle trace.

If a probe cable is too short, do not attempt to extend the length of the cable by adding a piece of common coaxial cable. The cable usually used for probes is much different than common 50 or 75-Ω coax. In addition the compensating capacitor in the probe is chosen to compensate for the provided length of cable. It usually will not have enough range to compensate for extra lengths.

The shortest ground lead possible should be used from the probe to the circuit ground. Long ground leads are inductors at high frequencies. In these circuits they cause ringing and other undesirable effects.

### Digital Oscilloscopes

The classic oscilloscope just discussed has existed for over 50 years. However, the cost of the oscilloscope has dropped with the widespread use of semiconductor technology and with this technology has come the digital oscilloscope. This type of oscilloscope has quickly gone from a laboratory oddity to an affordable tool in reach of the active experimenter. The design of a digital oscilloscope uses microcomputer technology.

Regular or "analog" scopes present relative changes on the screen, such as needed in RF work. Digital oscilloscopes can store,

(A)

(B)

**Fig 26.35 — Comparison of an analog storage scope waveform (A) and that produced by a digital storage oscilloscope (B). Notice that the digital samples in B are not continuous, which may leave the actual shape of the waveform in doubt for the fastest rise time displays the scope is capable of producing. Technology is continually improving the performance of digital scopes.**

change and compare waveforms. They can present words and values on the screen and even permit computer control of the scope. For many applications digital scopes are far better than analog scopes; they can give much more information.

Some digital oscilloscopes that are in the price range of the experimenter do not have a CRT; they use a personal computer to display the result. Measurement parameters are adjusted via the computer keyboard, rather than with front-panel knobs and switches. Contemporary digital scopes may be no more than a plug-in card for a PC.

Unfortunately, if the sample rate is not high enough, very fast signal changes between sampling points do not appear on the display. For example Fig 26.35 shows one signal measured on both analog and digital scopes. The large spikes in the analog scope display are not visible on the digital scope. The sampling frequency of the digital scope is not fast enough to store the higher frequency components of the waveform.

### Storage Oscilloscopes

Storage scopes are now showing up on the surplus markets at prices attractive to many amateurs. The CRTs, however, are fragile, extremely expensive and often the first component to wear out; they

**Fig 26.36 — Lissajous figures may be used to compare two different frequencies (see text).**

are not available used.

Storage scopes consist of an analog scope with special long-persistence (15 to 120 s) CRTs that allow them to capture single-shot events. Included in the scope design are circuits that allow the screen to hold whatever has been displayed for a preset period of time. For example, suppose it was necessary to determine the switching time of a switch contact that closes every 10 seconds. If seen on a regular oscilloscope the trace of the switch voltage will fade long before it is possible to measure the switch time visually.

A newer version of the storage scope is the digital storage oscilloscope (DSO). The DSO uses a high-speed semiconductor memory which is continually read back to the display so that the waveform can be viewed for as long as necessary. The DSO function is often included in digital scopes.

### Lissajous Figures

When ac voltages are applied to both sets of deflecting plates in the oscilloscope CRT, the pattern on the screen depends on the relative amplitudes, frequencies and phases of the two input voltages. If the ratio between the two frequencies is constant and can be expressed in integers, a stationary pattern will be produced.

The stationary patterns obtained in this way are called Lissajous figures. Examples of some of the simpler Lissajous figures are given in Fig 26.36. The ratio of the two frequencies can be found by counting the loops on one vertical and horizontal sides. In C there are three loops along a horizontal edge and only one along the vertical, so the ratio of the vertical frequency to the horizontal frequency is 3:1. Similarly, in E there are four loops along the horizontal edge and three along the vertical edge, giving a ratio of 4:3. If the

known frequency is applied to the horizontal plates, the unknown frequency is:

$$f_2 = \frac{n_2}{n_1} f_1 \quad (11)$$

where

$f_1$  = known frequency applied to horizontal plates

$f_2$  = unknown frequency applied to vertical plates

$n_1$  = number of loops along a vertical edge

$n_2$  = number of loops along a horizontal edge.

An important application of Lissajous figures is in the calibration of audio-frequency signal generators. For very low frequencies the 60-Hz power-line fre-

quency is held accurately enough to be used as a standard in most locations. The medium audio-frequency range can be covered by comparison with the 440- and 600-Hz modulation on WWV transmissions. It is possible to calibrate over a 10:1 range, both upward and downward from these frequencies and thus cover the audio range useful for voice communication.

## AN HF ADAPTER FOR NARROW-BANDWIDTH OSCILLOSCOPES

Fig 26.37 shows the circuit of a simple piece of test equipment that will allow you to display signals that are beyond the normal bandwidth of an inexpensive oscillo-

scope. This circuit was built to monitor modulation of a 10-m signal on a scope that has a 5-MHz upper-frequency limit. This design features a Mini-Circuits Labo-

ratory SRA-1 mixer. (See the Address List in the **References** chapter for contact information.) Any stable oscillator or VFO with an output of 10 dBm can be used for the local oscillator (LO), which mixes with the HF signal to produce an IF in the bandwidth of the oscilloscope.

The mixer can handle RF signal levels up to -3 dBm without clipping, so this was set as an upper limit for the RF input. A toroidal transformer coupler is constructed by winding a 31-turn secondary of #28-AWG wire on a 3E2A core, which has a 0.038-inch diameter. An FT-37-75 is suitable. The primary is a piece of coaxial cable passed through the core center. The coupler gives 30 dB of attenuation and has a flat response from 0.5 to 100 MHz. An additional 20-dB of attenuation was added for a total of 50 dB before the mixer. One-watt resistors will do fine for the attenuator. The completed adapter should be built into a shielded box.

This circuit, with a 25-MHz LO frequency, is useful on frequencies in the 20 to 30-MHz range with transmitters of up to 50-W power output. By changing the frequency of the LO, any frequency in the range of the coupler can be displayed on a 5-MHz-bandwidth oscilloscope. More attenuation will be required for higher-power transmitters. This circuit was described by Kenneth Stringham Jr., AE1X, in the Hints and Kinks column of February 1982 *QST*.

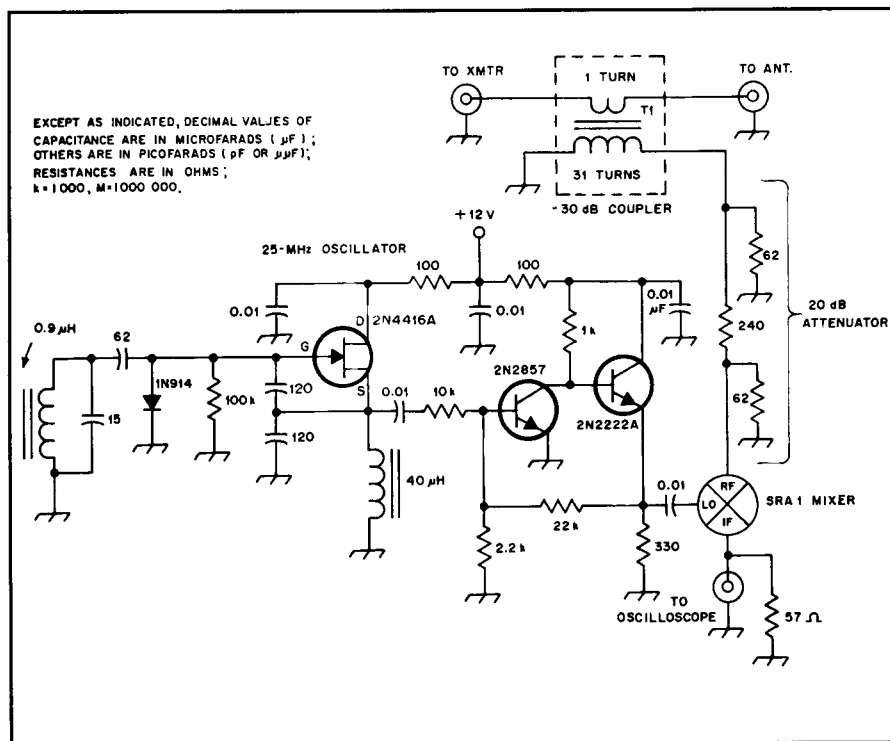

Fig 26.37 — This adapter displays HF signals on a narrow-bandwidth oscilloscope. It uses a 10-dBm 25-MHz LO, -30-dB coupler, 20-dB attenuator and diode-ring mixer. See text for further information.

## A CALIBRATED NOISE SOURCE

### NOISE FIGURE MEASUREMENT

One of the most important measurements in communications is the noise figure of a receiving set up. Relative measurements are often easy, while accurate ones are more difficult and expensive. One EME (moon bounce) station checks noise and system performance by measuring the noise of the sun reflected off the moon. While the measurement source (use of the sun and moon) is not expensive, the measuring equipment on 2 m consists of 48 antennas (each over 30 ft long). This measurement equipment is not for everyone!

The rest of us use more conventional noise sources and measuring techniques. Coverage of noise figure and its measurement appear in the **Transceivers** chapter of this *Handbook*.

Most calibrated and stable noise sources are expensive, but not this unit developed by Bill Sabin, WØIYH. It first appeared in May 1994 *QST*. When hams use a noise source, it is usually included in an RF bridge used to measure impedances and adjust antenna tuners. A somewhat different device (an *accurately calibrated and stable* noise source) is also useful. Combining a broadband RF noise source of known power output and a known output impedance with a true-RMS voltmeter, results in an excellent instrument for making interesting and revealing measurements on a variety of circuits hams commonly use. (Later on, some examples will be described.) The true-RMS voltmeter can be an RF voltmeter, a spectrum analyzer or an AF voltmeter at the output of a linear receiver.<sup>1</sup>

Calibrated noise generators and noise-figure meters are available at medium to astronomical prices. Here is a low-cost approach which can be used with reasonable confidence for many amateur applications where accuracy to tenths of a decibel is not needed, but where precision (repeatability) and comparative measurements are much more important. PC boards are available for this project.<sup>2</sup>

### Semiconductor Noise Diodes

Any Zener diode can be used as a source of noise. If, however, the source is to be calibrated and used for reliable measurements, avalanche diodes specially designed for this purpose are preferable by far.<sup>3</sup> A good noise diode generates its noise through a carefully controlled *bulk avalanche* mechanism which exists *throughout* the PN junction, not merely at the junction surfaces where unstable and unreliable surface effects predominate due to local breakdown and impurity.<sup>4</sup> A true noise diode has a very low *flicker noise* (1/f) effect and tends to create a uniform level of truly *Gaussian noise* over a wide band of frequencies.<sup>5</sup> In order to maximize its bandwidth, the diode also has very low junction capacitance and lead inductance.

This project uses the NOISE/COM NC302L diode. It consists of a glass, axial-lead DO-35 package and is rated for use from 10 Hz to 3 GHz, if appropriate construction methods are followed. Prior to sale, the diodes are factory aged for 168 hours and are well stabilized. NOISE/COM has kindly agreed to make these diodes available to amateur experimenters for the special price of \$10 each; the usual low-quantity price is about \$25.<sup>6</sup>

### Noise Source Design

The noise source presents two kinds of available output power. One is the thermal noise (−174 dBm/Hz at room temperature) when the diode is turned off. This is called  $N_{OFF}$ . The other is the sum of this same thermal noise and an “excess” noise,  $N_E$ , which is created by the diode when turned on, called  $N_{ON}$  (equivalent to  $N_{OFF} + N_E$ ). For accurate measurements, the output impedance of the test apparatus must be the same (on or off) so that the device under

test (DUT) always sees the same generator impedance. In Amateur Radio work, this impedance is usually 50  $\Omega$ , resistive. The circuit design must guarantee this condition.

For maximum frequency coverage, a PC-board layout and coax connector suitable for use at microwaves are needed. For lower frequency usage, a less stringent approach can be employed. Two noise sources are presented here. One is for the 0.5 to 500-MHz region and uses conventional components that many amateurs already have. The other is for the 1-MHz to 2.5-GHz range; it uses chip components and an SMA connector.

### Circuit Diagram and Construction

Figs 26.38 and 26.39 show the simple schematics of the two noise sources. In series with the diode is a 46.4- $\Omega$  resistor that combines with the dynamic resistance of the diode in the avalanche, noise generator mode (about 4  $\Omega$ ) to total about 50  $\Omega$ . When the applied voltage polarity is reversed, the diode is forward conducting and its dynamic resistance is still about 4  $\Omega$ , but the avalanche noise is now turned off. As a result, the noise source output impedance is always about 50  $\Omega$ . The 5-dB pad reduces the effect of any small impedance differences, so that the output impedance is nearly constant from the *on* to the *off* condition, and the SWR is less than 2:1.

Consider the noise situation of the noise diode when it is forward conducting. The resistance of the forward biased PN junction is a *dynamic* resistance. This dynamic resistance is *not* a source of thermal noise, since it is not an actual physical resistance such as in a resistor or lossy network. However, the 0.6-V forward drop across the PN junction does produce a shot noise effect. The mathematics of this shot noise shows that the noise power associated with this effect is only about 50% of the thermal noise power that would be available from a physical resistor having the same value as the dynamic resistance. Therefore, the forward biased junction does *not* add excess noise to the system.<sup>7</sup> There is an 1/f noise effect associated with this shot noise in the diode, but its corner frequency is at about 100 kHz and of no importance at higher frequencies. Also, the small amount of bulk resistance contributes a little thermal noise.

In order to maximize the unit's flatness

<sup>1</sup>W. Sabin, “Measuring SSB/CW Receiver Sensitivity,” *QST*, Oct 1992, pp 30-34. See also Technical Correspondence, *QST*, Apr 1993, pp 73-75.

<sup>2</sup>PC boards are available from FAR Circuits. See **References** chapter Address List; price, \$3.75 plus \$1.50 shipping. A PC-board template package is available free from the ARRL. Address your request for the SABIN NOISE SOURCE TEMPLATE to: Technical Department Secretary, ARRL, 225 Main St, Newington, CT 06111. Please enclose a business-size SASE.

<sup>3</sup>The term *Zener diode* is commonly used to denote a diode that takes advantage of avalanche effect, even though the Zener effect and the avalanche effect are not exactly the same thing at the device-physics level.

<sup>4</sup>The term *bulk avalanche* refers to the avalanche multiplication effect in a PN junction. A carrier (electron or hole) with sufficient energy collides with atoms and causes more carriers to be knocked loose. This effect “avalanches” and it occurs throughout the volume of the PN junction. This mechanism is responsible for the high-quality noise generation in a true noise diode.

<sup>5</sup>*Gaussian noise* refers to the instantaneous values of a noise voltage. These values conform to the Gaussian probability density function of statistics.

**Fig 26.42** — A view inside of the 1-MHz to 2.5-GHz noise source.

and the coupling capacitors. The power-supply voltage must be clean, well bypassed and set accurately. **Fig 25.40** shows a 0.5 to 500-MHz unit. This construction method satisfies quite well the electrical requirements wanted for this model. At 500 MHz, the return loss with respect to 50  $\Omega$  at the output jack decreased to 10 dB. A calibration chart (**Fig 26.41**) is attached to the unit's top for easy reference. **Fig 26.42** shows the inside of the 1-MHz to 2.5-GHz noise source.

### Calibrating the Noise Source

If the construction is solid, the calibration should last for a long time. There are two ways to calibrate the noise source. If the unit has been carefully constructed and its correct operation verified, NOISE/COM will calibrate home-built units over the desired frequency range for \$25 plus return shipping charges. Note that one factory calibrated unit can be used as a reference for many home calibrated units. **Fig 26.43** shows the NOISE/COM calibra-

**Fig 26.41** — Sample calibration chart for the 0.5 to 500-MHz noise source.

and frequency response bandwidth, noise-source construction methods should aim for RF circuit lead lengths as close to zero as possible as well as minimum inductance in the ground path

tion data for both models of prototype noise sources, including SWR data. The noise data is strictly valid only at room temperature, so it's necessary to avoid extreme temperature environments.

The second calibration method requires a signal generator with known output levels at the various desired calibration frequencies. One approach is to build a tunable weak-signal oscillator that can be compared to some accessible high-quality signal generator, using a sensitive receiver as a detector.<sup>8</sup> The level of the signal source in dBm is needed.

Access to a multistage attenuator is also desirable. Build the attenuator using the nearest 1% values of metal-film resistors, so that systematic errors are minimized. A total attenuation of 25 dB in 0.1-dB steps is desirable. Attenuator construction must be appropriate for use at the intended frequency range. In some cases, a high-frequency correction chart may be needed.

With the calibrated signal source and the attenuator feeding the receiver in an SSB or CW mode the techniques discussed in the reference of Note 1 should be used to determine the excess noise ( $N_E$ ) of the noise source and the noise bandwidth ( $B_N$ ) of the receiver.

### Excess Noise Ratio

A few words about excess noise ratio (ENR) are needed. It is defined as the ratio of excess noise to thermal noise. That is,

$$ENR = \frac{N_{ON} - N_{OFF}}{N_{OFF}} = \frac{N_E}{N_{OFF}} \quad (12)$$

When the noise source is turned on, its output is  $N_{OFF} + N_E$ . The ratio of  $N_{ON}$  to  $N_{OFF}$  is then

$$\begin{aligned} \frac{N_{ON}}{N_{OFF}} &= \frac{N_{OFF} + N_E}{N_{OFF}} \\ &= 1 + \frac{N_E}{N_{OFF}} = 1 + ENR \end{aligned} \quad (13)$$

Therefore, ENR is a measure of how much the noise increases and the noise generator can be calibrated in terms of its ENR.

Normalizing ENR to a 1-Hz bandwidth and converting to decibels, this is

$$ENR \text{ (dB)} = 174 \text{ (dBm / Hz)} + \frac{N_E \text{ (dBm)}}{B_N \text{ (Hz)}} \quad (14)$$

Prepare a calibration chart and attach it to the top of the unit (see Fig 26.41). If the

Frequency (MHz)	0.5 to 500 MHz Unit		1.0 to 2500 MHz Unit	
	ENR (dB)	SWR	NR (dB)	SWR
0.5	22.33	1.03		
1	22.38	1.03	21.38	1.03
10	22.45	1.04	21.46	1.03

1000			20.12	1.86
1500			20.00	2.06
2000			20.70	2.14
2500			21.51	1.88

Fig 26.43 — NOISE/COM calibration data for both prototype noise sources. The data is not universal; it varies from unit to unit.

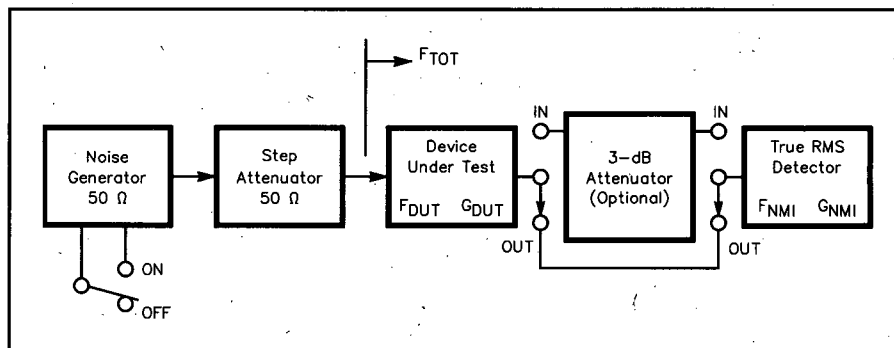

Fig 26.44 — Setup for measuring noise figure of a device under test (DUT).

unit is to be factory calibrated, first perform the calibration procedure to ensure everything is working properly. Remember, a factory calibrated unit can be used as a reference for other home calibrated units, once the calibration-transfer procedures have been worked out. This requires some careful thinking and proper techniques. Generally speaking, a NOISE/COM calibration is the best choice.

### Noise-Figure Measurement

The thermal noise power available from the attenuator remains constant for any value of attenuator setting. But the excess noise and therefore the ENR (in dB) due to the noise diode is equal to the calibration point of the source minus the setting (in dB) of the attenuator.

The noise-figure measurement of a device under test (DUT) uses the Y method and the setup in Fig 26.44. If the DUT has a noise-generator input and a true-RMS noise-measuring instrument at the output,

then the total output noise (including the contribution of the measuring instrument) with the noise generator turned off is

$$N_{OFF(TOT)} = kTB_N F_{TOT} G_{DUT} G_{NMI} \quad (15)$$

where

$kTB_N$  = thermal noise,

$G_{DUT}$  = gain of the DUT,

$G_{NMI}$  = gain of the noise-measuring instrument, and

$F_{TOT}$  = noise factor of the combination of the DUT and the noise-measuring instrument.

When the noise generator is turned on, the output noise is

$$N_{ON(TOT)} = kTB_N F_{TOT} G_{DUT} G_{NMI} + (ENR) kTB_N G_{DUT} G_{NMI} \quad (16)$$

Where the last term is the contribution of excess noise by the noise generator. Note that none of these values is in dB or dBm.

<sup>8</sup>W. Hayward and D. DeMaw, *Solid State Design for the Radio Amateur* (Newington: ARRL, 1986).

If we divide equation 16 by equation 15 and say that the ratio

$$\frac{\text{NON}(\text{TOT})}{\text{NOFF}(\text{TOT})} = Y \quad (17)$$

then,

$$\frac{F_{\text{TOT}} + \text{ENR}}{F_{\text{TOT}}} = 1 + \frac{\text{ENR}}{F_{\text{TOT}}}$$

Note that  $kTBN$ ,  $G_{\text{DUT}}$  and  $G_{\text{NMI}}$  disappear, so that these quantities need not be known to measure noise factor. If we solve equation 17 for  $F_{\text{TOT}}$ , we get the noise factor

$$F_{\text{TOT}} = \frac{\text{ENR}}{Y - 1} \quad (18)$$

If the noise output doubles (increases by 3 dB) when we turn on the noise source, then  $Y = 2$  and the noise factor is numerically equal to the excess noise ratio (ENR). If the attenuator steps are not fine enough or if the attenuator is not reliable over the entire frequency range, use equation 18 to get a better answer. (It's much simpler to use a good fine-step attenuator.) The value of  $F_{\text{TOT}}$  is that of the DUT in cascade with the noise-measuring instrument. To find  $F_{\text{DUT}}$ , we must know the noise factor  $F_{\text{NMI}}$  of the noise-measuring instrument and  $G_{\text{DUT}}$  and then use the Friis formula, unless  $G_{\text{DUT}}$  is very large (as it would be if the DUT were a high-gain receiver (see footnote 1).

$$F_{\text{DUT}} = F_{\text{TOT}} - \frac{F_{\text{NMI}} - 1}{G_{\text{DUT}}} \quad (19)$$

The validity of equation 19 (if we need to use it) requires that the noise bandwidth of the noise-measuring instrument be less than the noise bandwidth of the DUT (see the referent of Note 1). Verify this before proceeding.

There's another advantage to using the power-doubling method. If the 3-dB attenuator of Fig 26.44 is used to maintain a constant noise level into the following stages and the RMS meter, this means that the noise factor, using the calibration scale and the input attenuator (without using equation 18), is

$$F_{\text{DUT}} = \text{ENR} + \frac{1}{G_{\text{DUT}}} \quad (20)$$

If  $G_{\text{DUT}}$  is large, then the last term can be neglected. If  $G_{\text{DUT}}$  is small, we need to know its value. However, we do not need to know the noise factor  $F_{\text{NMI}}$  of the circuitry after the DUT, as we did in the previous discussion.

The 3-dB attenuator method also re-

moves all restrictions regarding the type of noise measuring instrument, since the meter reading is now used only as a reference point. This last statement applies only when two noise (or two signal generator) inputs are being compared.

### Frequency Response Measurements

The noise generator, in conjunction with a spectrum analyzer, is an excellent tool for measuring the frequency response of a DUT, if the noise source is much stronger than the internal noise of the DUT and that of the spectrum analyzer. Many spectrum analyzers are not equipped with tracking generators, which can be quite expensive for an amateur's budget.

The spectrum analyzer needs to be calibrated for a noise input, if accurate amplitude measurements are needed, because it responds differently to noise signals than to sine-wave signals. The envelope detection of noise, combined with the logarithmic amplification of the spectrum analyzer, creates an error of about 2.5 dB for a noise signal (the noise is that much greater than the instrument indicates). Also, the noise bandwidth of the IF filter is different from its resolution bandwidth. Some modern spectrum analyzers have internal DSP algorithms that make the corrections so that external noise sources and also carrier-to-noise ratios, normalized to some noise bandwidth like 1.0 Hz, can be measured with fair accuracy if the input noise is a few decibels above thermal. One example is the Tektronix Model 2712. If only relative response readings are needed, then these corrections are not needed.

Also, the noise source itself can be used to establish an accurate reference level (in dBm) on the screen. An accurate, absolute measurement with the DUT in place will then be this reference level (in dBm), plus the increment in decibels produced by the DUT.

The noise-generator output can be viewed as a collection of sine waves separated by, say, 1 Hz. Each separated frequency "bin" has its own Gaussian amplitude and random phase with respect to all the others. So the DUT is simultaneously looking at a collection or "ensemble," of input signals. As the spectrum analyzer frequency sweeps, it looks simultaneously at all of the DUT frequencies that fall within the spectrum analyzer's IF noise bandwidth. The spectrum display is thus the "convolution" of the IF filter frequency response and the DUT frequency

response. If the DUT is a narrow filter, a very narrow resolution and a slow sweep are needed in the spectrum analyzer. In addition, the analyzer's video, or post-detection, filter has a narrow bandwidth and also requires some settling time to get an accurate reading. So, some experience and judgment are required to use a spectrum analyzer this way.

### Using Your Station Receiver

Your station receiver can also be used as a spectrum analyzer. Place a variable attenuator between the DUT and the receiver. As you tune your receiver, in a narrow CW mode, adjust the attenuator for a constant reference level receiver output. The attenuator values are inversely related to the frequency response.

A calibrated noise source with an adjustable attenuator that can be easily switched into a receiver antenna jack is an excellent tool for measuring antenna noise level or incoming weak signal level (in dBm) or for establishing correct receiver operation.

The noise source can also be combined with a locally generated data-mode waveform of a known dBm value to get an approximate check on modem performance or to make adjustments that might assure correct operation of the system. The rigorous evaluation of system performance requires special equipment and techniques that may be unavailable at most amateur stations. Or, you could evaluate the intelligibility improvement of your SSB transmitter's speech processor in a noise background.

### Summary

The calibrated, flat-spectrum noise generator described in this article is quite a useful instrument for amateur experimenters. Its simplicity and low cost make it especially attractive. Getting a good calibration is the main challenge, but once it is achieved, the calibration lasts a long time, if the right diode is used. The ENR of the units described here is in the range of 20 dB. Use of a high-quality, external, 10-dB attenuator barrel will get into the range of 10-dB ENR. If the unit is sent to NOISE/COM the attenuator should also be sent, with the request that it be included in the calibration. That attenuator then "belongs" to the noise source and should be so tagged. If the attenuator is of high quality, the output SWR will also be improved. NOISE/COM suggests periodic recalibration, at your discretion.

## A NOISE BRIDGE FOR 1.8 THROUGH 30 MHz

The noise bridge, sometimes referred to as an antenna noise bridge or RX noise bridge, is an instrument that measures the impedances of antennas or other electrical circuits. The unit shown in Fig 26.45 provides adequate accuracy for most measurements in the 1.8- through 30-MHz range. Battery operation and small physical size make this unit ideal for remote-location use. This classic bridge circuit was updated by Mark Shelhamer, WA3YNO. Additional information about using the noise bridge for transmission-line measurements appears in that article and in the **Transmission Line and Antenna Measurements** chapter of *The ARRL Antenna Book*. A detector, such as the station receiver, is required for operation.

The noise bridge consists of two parts: the noise generator and the bridge circuitry. See Fig 26.46. A 6.8-V Zener diode serves as the noise source. The broadband noise signal is amplified by U1 and associated components to produce an approximate S9 signal in the receiver.

The bridge portion of the circuit consists of T1, C1 and R1. T1 is a ferrite core wound as shown in the schematic detail. This design eliminates phase shift and the ferrite

core has sufficient permeability to eliminate low-frequency resistance shift. One winding of T1 couples noise energy into the bridge circuit. The remaining two windings are each in one arm of the bridge. C1 and R1 complete the known arm; the UNKNOWN circuit with C3 comprises the remainder of the bridge. The terminal labeled RCVR is for connection to the detector.

The reactance range of a noise bridge depends on several factors, including operating frequency, value of the series capacitor (C3 in the figure) and the range of the variable capacitor (C1 in the figure). The zero-reactance point occurs when C1 is either nearly fully meshed or fully unmeshed.

### Construction

The noise bridge can be put in a home-made aluminum enclosure that measures  $5 \times 2\frac{3}{8} \times 3\frac{3}{4}$  inches. Many of the circuit components are mounted on a circuit board that is fastened to the rear wall of the cabinet. The circuit-board layout keeps the lead lengths to the board from the bridge and coaxial connectors to a minimum.

Potentiometer R1 must be mounted carefully. For accurate readings it must be

very well insulated from ground. In the prototype the control is mounted on a piece of Plexiglas, which was fastened to the chassis with a piece of aluminum angle stock. Additionally, a  $\frac{1}{4}$ -inch control-shaft coupling and a length of phenolic rod were used to keep the control away from the front panel. Use a high-quality potentiometer to ensure good measurement results.

The variable capacitor is easier to mount because the rotor is grounded. It should be a high-quality unit. Two female RF fittings on the rear panel are connected to a detector (receiver) and to the UNKNOWN circuit. Plastic insulated phono connectors should *not* be used because they might influence bridge accuracy at higher frequencies. Miniature coaxial cable (RG-174) is used for the connection between the RCVR connector and circuit board. Attach one end of C3 to the circuit board and the other directly to the UNKNOWN circuit connector.

### Bridge Compensation

Stray capacitance and inductance in the bridge circuit can affect impedance readings. If a very accurate bridge is required, use the next steps to make readings more accurate.

Good calibration loads are necessary to check the accuracy of the noise bridge. Four are needed here: a 0- $\Omega$  (short circuit) load, a 50- $\Omega$  load, a 180- $\Omega$  load and a variable-resistance load. The short-circuit and fixed-resistance loads are used to check the accuracy of the noise bridge; the variable-resistance load is used when measuring coaxial-cable loss.

Construction details of the loads are shown in Fig 26.47. Each load is constructed inside a connector. The leads should be kept as short as possible. The resistors must be noninductive (not wire wound). Carbon-composition ( $\frac{1}{4}$ -W) resistors should work fine. The potentiometer in the variable-resistance load is a miniature PC-mount unit with a maximum resistance of 100  $\Omega$ , or less. The potentiometer wiper and one of the end leads are connected to the center pin of the connector; the other lead is connected to ground.

### Stray Capacitance

Stray capacitance on the variable-resistor side of the bridge tends to be higher than that on the unknown side. This is because of parasitic capacitance in the variable resistor, R1.

The effect of parasitic capacitance is most easily detected using the 180- $\Omega$  load. Mea-

Fig 26.45 — Noise bridge construction details. Press-on lettering is used for the calibration marks. Note that the potentiometer must be isolated from ground.

Fig 26.47 — Loads used to check and calibrate a noise bridge are built into a PL-259 shell. Leads should be kept as short as possible to minimize parasitic inductance. The connector shell is screwed in place after construction and is not shown in the figure. (A) is a short circuit; (B) depicts a 50- $\Omega$  load; (C) is a 180- $\Omega$  load; (D) shows a variable-resistance load used to determine the loss in a coaxial cable.

sure and record the actual resistance of the load,  $R_L$ . Connect the load to the UNKNOWN connector, place S2 in the  $X_L$  position, tune the receiver to 1.8 MHz and null the bridge. (See "Finding the Null" below for tips.) Use an ohmmeter across R1 to measure its dc resistance. The magnitude of the stray capacitance can be calculated by:

$$C_P = C_S \left( \sqrt{\frac{R_1}{R_L}} - 1 \right) \quad (21)$$

where

$R_L$  = load resistance (as measured), ohms

$R_1$  = resistance of the variable resistor, ohms

$C_S$  = series capacitance (either C3 or C4, whichever is selected), pF.

We can compensate for  $C_P$  by placing a variable capacitor,  $C_C$ , in the side of the bridge with lesser stray capacitance. If  $R_1$  is greater than  $R_L$ , stray capacitance is greater on the variable resistor side of the bridge: Place  $C_C$  between point U (on the circuit board) and ground. If  $R_1$  is less than  $R_L$ , stray capacitance is greater on the unknown side: Place  $C_C$  between point B and ground.

If the needed compensating capacitance is only a few pF, you can use a gimmick capacitor (made by twisting two short pieces of insulated, solid wire together) for  $C_C$ . A gimmick capacitor is adjusted by trimming its length.

Compensate the bridge by setting the dc resistance of R1 equal to  $R_L$ . With the bridge at 1.8 MHz, alternately adjust  $C_C$

and C1 to obtain a null.

### Stray Inductance

Parasitic inductance, if present, should be only a few tens of nH. This represents a few ohms of inductive reactance at 30 MHz. The effect is best observed by reading the reactance of the 0- $\Omega$  test load at 1.8 MHz and 30 MHz; the indicated reactance should be the same at both frequencies.

If the reactance reading decreases as frequency is increased, parasitic inductance is greater in the known arm and compensating inductance is needed between point U and C3. If the reactance increases with frequency, the unknown-arm inductance is greater and compensating inductance should be placed between point B and R1.

Compensate for stray inductance by placing a single-turn coil, made from a 1 to 2-inch length of solid wire, in the appropriate arm of the bridge. Adjust the size of this coil until the reactance reading remains constant from 1.8 to 30 MHz.

### Calibration

Good calibration accuracy is necessary for accurate noise-bridge measurements. Calibration of the resistance scale is straightforward. To do this, tune the receiver to a frequency near 10 MHz. Attach the 0- $\Omega$  load to the UNKNOWN connector and null the bridge. This is the zero-resistance point; mark it on the front-panel resistance scale. The rest of the resistance range is calibrated by adjusting R1, measuring R1 with an accurate ohmmeter, calculating the increase from the zero point and marking the increase on the front panel.

Most bridges have the reactance scale marked in capacitance because capacitance does not vary with frequency. Unfortunately, that requires calibration curves or complex calculations to find the load reactance. An alternative method is to mark the reactance scale in ohms at a reference frequency of 10 MHz. This method calibrates

**Table 26.6**

### Noise Bridge Calibration with Coaxial Cable

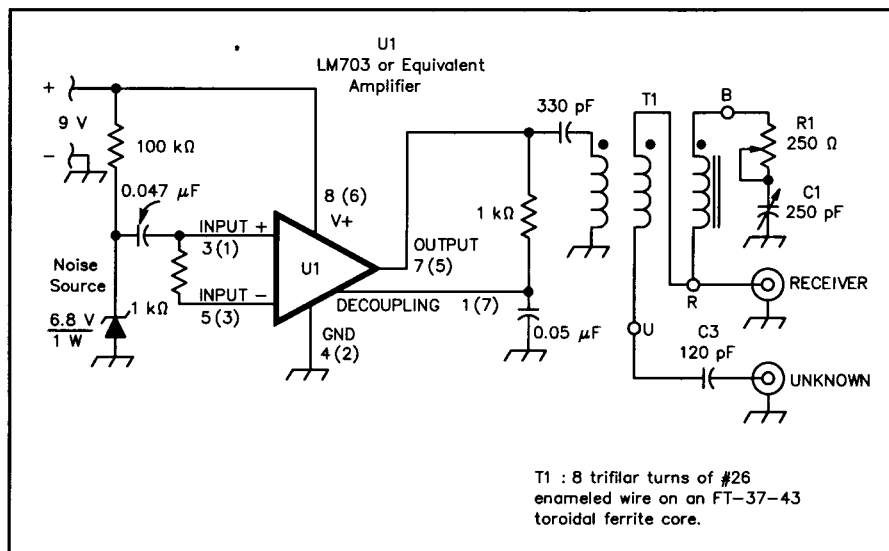

This data is for Radio Shack RG-8M cable ( $R_0 = 52.5 \Omega$ ) cut to exactly  $\lambda/4$  at 10 MHz; the reactances and capacitances shown correspond to this frequency.

**Fig 26.46 — Noise bridge schematic.** The pin numbers on U1 refer to a metal can LM703 or the NTE/ECG replacement. Those in parentheses are for a National Semiconductor mini-DIP LM703N. See the text for placement of compensation C or L at points B, U or R.

the bridge near the center of its range and shows reactance directly, but it requires a simple calculation to scale the reactance reading for frequencies other than 10 MHz. The scaling equation is:

$$X_{u(f)} = X_{u(10)} \frac{10}{f} \quad (22)$$

where

$f$  = frequency, MHz

$X_{u(10)}$  = reactance of the unknown load at 10 MHz.

$X_{u(f)}$  = reactance of the unknown load at  $f$ .

A shorted piece of coaxial cable serves as a reactance source. (The reactance of a shorted, low-loss coaxial cable is dependent only on the cable length, the measurement frequency and the cable characteristic impedance.) Radio Shack RG-8M is used here because it is easy to get, has relatively low loss and has an almost purely resistive characteristic impedance. Prepare the calibration cable as follows:

1. Cut a length of coaxial cable that is slightly longer than  $\lambda/4$  at 10 MHz (about 20 ft for RG-8M). Attach a suitable connector to one end of the cable; leave the other end open circuited.
2. Connect the 0- $\Omega$  load to the noise bridge UNKNOWN connector and set the receiver frequency to 10 MHz. Adjust the noise bridge for a null. Do not adjust the reactance control after the null is found.
3. Connect the calibration cable to the bridge UNKNOWN terminal. Null the bridge by adjusting only the variable resistor and the receiver frequency. The receiver frequency should be less than 10 MHz; if it is above 10 MHz, the cable is too short and you need to prepare a longer one.

4. Gradually cut short lengths from the end of the coaxial cable until you obtain a null at 10 MHz by adjusting only the resistance control. Then connect the cable center and shield conductors at the open end with a short length of braid. Verify that the bridge nulls with zero reactance at 20 MHz.

5. The reactance of the coaxial cable (normalized to 10 MHz) can be calculated from:

$$X_{i(10)} = R_0 \frac{f}{10} \tan \left( 2\pi \frac{f}{40} \right) \quad (23)$$

where

$X_{i(10)}$  = cable reactance at 10 MHz

$R_0$  = characteristic resistance of the coaxial cable (52.5  $\Omega$  for Radio Shack RG-8M)

$f$  = frequency in MHz.

The results have less than 5% error for reactances less than 500  $\Omega$ , as long as the test-cable loss is less than 0.2 dB. This error becomes significantly less at lower reactances (2% error at 300  $\Omega$  for a 0.2-dB loss cable). The loss in 18 ft of RG-8M is 0.13 dB at 10 MHz. Reactance data for Radio Shack RG-8M is given in **Table 26.6**.

With the prepared cable and calibration values on hand, go on to calibrate the reactance scale. Tune the receiver to the appropriate frequency for the desired reactance (given in the table or found using the equation). Adjust the resistance and reactance controls to null the bridge. Mark the reactance reading on the front panel. Repeat this process until all desired reactance values have been marked. The resistance values needed to null the bridge during this calibration procedure may be

quite high (more than 100  $\Omega$ ) at the higher reactances.

This calibration method is much more accurate than using fixed capacitors across the UNKNOWN connector. Also, you can calibrate a noise bridge in less than an hour using this method.

### Finding the Null

In use, a receiver is attached to the RCVR connector and some load of unknown value is connected to the UNKNOWN terminal. The receiver allows us to hear the noise present across the bridge arms at the frequency the receiver is tuned to. The strength of the noise signal depends on the strength of the noise-bridge battery, the receiver bandwidth/sensitivity and the impedance difference between the known and unknown bridge arms. The noise is stronger and the null more obvious with wide receiver passbands. Set the receiver to the widest bandwidth AM mode available.

When the impedances of the known and unknown bridge arms are equal, the voltage across the receiver is minimized; this is a null. In use, the null may be difficult to find because it appears only when both bridge controls approach the values needed to balance the bridge.

To find the null, set C1 to midscale, sweep R1 slowly through its range and listen for a reduction in noise (it's also helpful to watch the S meter). If no reduction is heard, set R1 to midrange and sweep C1. If there is still no reduction, begin at one end of the C1 range and sweep R1. Change C1 by about 10% and sweep R1 with each change until some noise reduction appears. Once noise reduction begins, adjust C1 and R1 alternately for minimum signal.

## A SIGNAL GENERATOR FOR RECEIVER TESTING

The oscillator shown in Fig 26.48 and Fig 26.49 was designed for testing high-performance receivers. Parts cost for the oscillator has been kept to a minimum by careful design. While the stability is slightly less than that of a well-designed crystal oscillator, the stability of the unit should be good enough to measure most amateur receivers. In addition, the ability to shift frequency is important when dealing with receivers that have spurious responses. More importantly, LC oscillators with high-Q components often have much better phase noise performance than crystal oscillators, because of power limitations in the crystal oscillators (crystals are easily damaged by excessive power).

The circuit is a Hartley oscillator followed by a class-A buffer amplifier. A 5-V regulator is used to keep the power supply output stable. The amplifier is cleaned up by a seven-element

Chebyshev low-pass filter, which is terminated by a 6-dB attenuator. The attenuator keeps the filter working properly, even with a receiver that has an input impedance other than 50  $\Omega$ . A receiver designed to work with a 50- $\Omega$  system may not have a 50- $\Omega$  input impedance. The +4 dBm output is strong enough for most receiver measurements. It may even be too strong for some receivers. Note that sensitive components like crystal filters may require a step attenuator to lower the output level.

### Construction

This unit is built in a box made of double-sided circuit board. Its inside dimensions are 1x2.2x5 inches (HWD). The copper foil of the circuit board makes an excellent shield, while the fiberglass helps temperature stability. Capacitor C2 should be soldered di-

rectly across L1 to ensure high Q. Since this is an RF circuit, leads should be kept short. While silver mica capacitors have slightly better Q, NP0 capacitors may offer better stability. Mounting the three inductors orthogonal (axis of the inductors 90° from each other) reduced the second-order harmonic by 2 dB when it was compared to the first unit that was made.

### Alignment and Testing

The output of the regulator should be +5 V. The output of the oscillator should be +4 dBm (2.5 mW) into a 50- $\Omega$  load. Increasing the value of C3 will increase the power output to a maximum of about 10 mW. The frequency should be around 3.7 MHz. Additional capacitance across L1 (in parallel with C2) will lower the frequency if desired, while the trimmer capacitor (C1) specified will allow adjustment to a specific frequency. The drift

of one of the first units made was 5 Hz over 25 minutes after a few minutes of warm up. If the warm-up drift is large, changing C2 may improve the situation somewhat. For most receivers, a drift of 100 Hz while you are doing measurements is not bad.

Fig 26.48 — A low-cost LC oscillator for receiver measurements. Toroidal cores are used for all of the inductances.

## HYBRID COMBINERS FOR SIGNAL GENERATORS

Many receiver performance measurements require two signal generators to be attached to a receiver simultaneously. This, in turn, requires a combiner that isolates the two signal generators (to keep one generator from being frequency or phase modulated by the other). Commercially made hybrid combiners are available from Mini-Circuits Labs (see the Address List in the **References** chapter).

Alternatively, a hybrid combiner is not difficult to construct. The combiners described here (see Fig 26.50) provide 40 to 50 dB of isolation between ports (connections) while attenuating the desired signal paths (each input to output) by 6 dB. The 50- $\Omega$  impedance of the system is kept constant (very important if accurate measurements are to be made).

The combiners are constructed in small boxes made from double-sided circuit-board material. Each piece is

soldered to the next one along the entire length of the seam. This makes a good RF-tight enclosure. BNC coaxial fittings are used on the units shown. However, any type of coaxial connector can be used. Leads must be kept as short as possible and precision resistors (or matched units from the junk box) should be used. The circuit diagram for the combiners is shown in Fig 26.51.

Fig 26.50 — The hybrid combiner on the left is designed to cover the 1 to 50-MHz range; the one on the right 50 to 500 MHz.

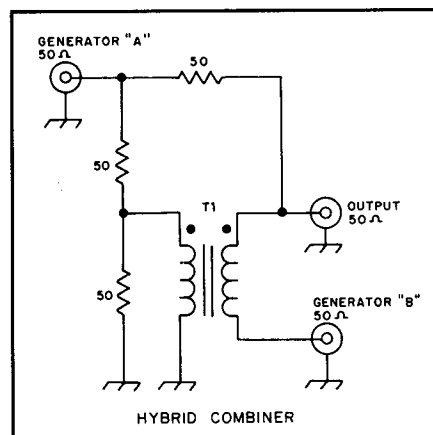

Fig 26.51 — A single bifilar wound transformer is used to make a hybrid combiner. For the 1 to 50-MHz model, T1 is 10 turns of #30 enameled wire bifilar wound on an FT-23-72 ferrite core. For the 50 to 500-MHz model, T1 consists of 10 turns of #30 enameled wire bifilar wound on an FT-23-63 ferrite core. Keep all leads as short as possible when constructing these units.

## Return Loss Bridges

Return loss is a measure of how closely an impedance matches a reference impedance in phase angle and magnitude. If the reference impedance equals the measured impedance level with a  $0^\circ$  phase difference it has a return loss of infinity. **Fig A** shows basic return-loss measurement setups. Return-loss bridges are good for measuring filter response because return loss measurements are a more sensitive measure of passband response than insertion-loss measurements.

### A 100 Hz to 100-kHz Return-Loss Bridge

Ed Wetherhold, W3NQN, has developed a low-frequency return-loss bridge (RLB) that can be adapted to different impedance levels. (See **Fig B**.) This bridge is

used primarily for testing passive-LC filters that have been designed to work at a certain impedance level. Return-loss measurements require that the signal generator and RLB match the specific filter impedance level.

The characteristic impedance of this RLB is set by the values of four resistors ( $R1 = R2 = R3 = R4 =$  characteristic impedance). Ed mounted the four resistors on a plug-in module and placed their interconnections on the socket. Additional modules may be built for any impedance.

**Table A** provides computed values of return loss for several known loads and a  $500\text{-}\Omega$  RLB. If you build this RLB, use the values in the table to check its operation. For this frequency range, use an ac voltmeter in place of the power meter shown in **Fig A**. Choose one with good ac response well above 100 kHz.

Ed originally described this bridge circuit in an article published in 1993. That article provides complete construction details. Reprints are available from Ed Wetherhold, W3NQN (for \$3). (For contact information, see the **References** chapter Address List.) The RLB shown is useful from 100 Hz to 100 kHz.

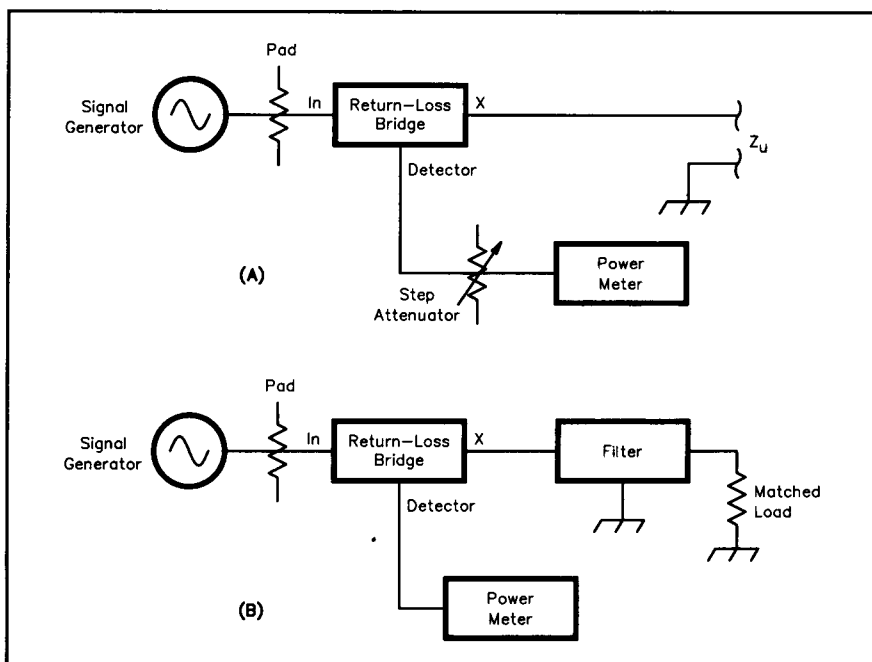

### An RF Return-Loss Bridge

At HF and higher frequencies, return-loss bridges are used as shown in **Fig A** for making measurements in RF circuits. The schematic of a simple bridge is shown in **Fig C**. (Notice that the circuit is identical to that of a hybrid combiner.) It is built in a small box with short leads to the coax connectors. Either  $49.9\text{-}\Omega$  1% metal-film or  $51\text{-}\Omega$   $\frac{1}{4}$ -W carbon resistors may be used. The transformer is wound with 10 bifilar turns of #30 enameled wire on a high permeability ferrite core such as an FT-23-43 or similar.

Apply the output of the signal generator to the RF INPUT port of the RLB. It may be necessary to attenuate the generator output to avoid overloading the amplifier under test. Connect the bridge DETECTOR port to a power meter through a step attenuator and leave the UNKNOWN port of the bridge open circuited. Set the step attenuator for a relatively high level of attenuation and note the power meter indication.

Now connect the unknown impedance,  $Z_u$ , to the bridge. The power meter reading will decrease. Adjust the step attenuator to produce the same reading obtained when the UNKNOWN port was open circuited. The difference between the two settings of the attenuator is the return loss, measured in dB.

The unknown impedance measured by this technique is not limited to amplifier inputs. Coax cable attached to an antenna, a filter, or any other fixed impedance device can be characterized by return loss. Return

**Fig A** — **A** shows a setup to measure an unknown impedance with a return loss bridge. **B** is for measuring filter response.

**Table A**

**Performance and Test Data for the 100-Hz to 100-kHz RLB**

Bridge and signal-generator impedance = 500  $\Omega$

**Bridge Directivity**

Frequency	Return Loss (dB, Unknown = 500- $\Omega$ )
100 Hz to 10 kHz	> 45
10 kHz to 80 kHz	40
80 kHz to 100 kHz	30

**Return Loss of Known Resistive Loads**

$$R_{LOAD} = LF \times Z_{BRIDGE}$$

where

$R_{LOAD}$  = Load resistance, ohms

LF = Load factor

$Z_{BRIDGE}$  = characteristic bridge impedance, ohms.

LF	Return Loss (dB)
5.848	3
3.009	6
1.925	10
1.222	20
1.065	30

loss is measured in dB, and it is related to a quantity known as the voltage reflection coefficient,  $r$ :

$$RL = -20 \log |\rho|$$

$$|\rho| = 10^{-\frac{RL}{20}}$$

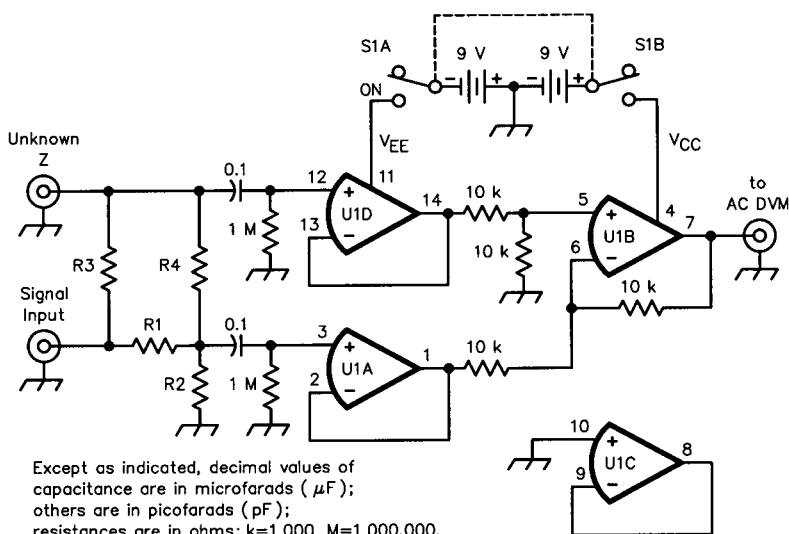

where

RL = return loss, dB

$\rho$  = voltage reflection coefficient.

The relationship of return loss to SWR is:

$$SWR = \frac{1 + |\rho|}{1 - |\rho|}$$

**Fig B — An active low-frequency RLB. U1 is an LM324 quad op amp. R1, R2, R3 and R4 are 1/4-W, 1% resistors with the same value as the output impedance of the signal generator and the input impedance of the test circuit.**

**Fig C — An RLB for RF. Keep the lead lengths short. Wind the transformer on a high-permeability ferrite core. Use either 51- $\Omega$  carbon or 49.9- $\Omega$  1% metal-film resistors.**

# Receiver Performance Tests

Comparing the performance of one receiver to another is difficult at best. The features of one receiver may outweigh a second, even though its performance under some conditions is not as good as it could be. Although the final decision on which receiver to purchase will more than likely be based on personal preference and cost, there are ways to compare receiver performance characteristics. Some of the more important parameters are sensitivity, blocking dynamic range and two-tone IMD dynamic range.

Instruments for measuring receiver performance should be of suitable quality and calibration. Always remember that accuracy can never be better than the tools used to make the measurements. Common instruments used for receiver testing include:

- Signal generators
- Hybrid combiner
- Audio ac voltmeter
- Distortion meter (FM measurements only)
- Noise figure meter (only required for noise figure measurements)
- Step attenuators (10 dB and 1 dB steps are useful)

Signal generators must be calibrated accurately in dBm or  $\mu\text{V}$ . The generators should have extremely low leakage. That is, when the output of the generator is switched off, no signal should be detected at the operating frequency with a sensitive receiver. Ideally, at least one of the signal generators should be capable of amplitude modulation. A suitable lab-quality piece would be the HP-8640B.

While most signal generators are calibrated in terms of microvolts, the real concern is not with the voltage from the generator but with the power available. The unit that is used for most low-level RF work is the milliwatt, and power is often specified in decibels with respect to 1 mW (dBm). Hence, 0 dBm would be 1 mW. The dBm level, in a 50- $\Omega$  load, can be calculated with the aid of the following equation:

$$\text{dBm} = 10 \log_{10} \left[ 20 (V_{\text{RMS}})^2 \right] \quad (24)$$

where

dBm = power with respect to 1 mW  
 $V$  = RMS voltage available at the output of the signal generator.

The convenience of a logarithmic power unit such as the dBm becomes apparent when signals are amplified or attenuated. For example, a  $-107$  dBm signal that is applied to an amplifier with a gain of

20 dB will result in an output increased by 20 dB. Therefore in this example  $(-107 \text{ dBm} + 20 \text{ dB}) = 87 \text{ dBm}$ . Similarly, a  $-107$  dBm signal applied to an attenuator with a loss of 10 dB will result in an output of  $(-107 \text{ dBm} - 10 \text{ dB})$  or  $-117 \text{ dBm}$ .

A hybrid combiner is a three-port device used to combine the signals from a pair of generators for all dynamic range measurements. It has the characteristic that signals applied at ports 1 or 2 appear at port 3 and are attenuated by 3 dB. However, a signal from port 1 is attenuated 30 or 40 dB when sampled at port 2. Similarly, signals applied at port 2 are isolated from port 1 some 30 to 40 dB. The isolating properties of the box prevent one signal generator from being frequency or phase modulated by the other. A second feature of a hybrid combiner is that a 50- $\Omega$  impedance level is maintained throughout the system.

Audio voltmeters should be calibrated in dB as well as volts. This facilitates easy measurements and eliminates the need for cumbersome calculations. Be sure that the step attenuators are in good working order and suitable for the frequencies involved. A distortion meter, such as the Hewlett-Packard 339A, is required for FM sensitivity measurements and a noise figure meter, such as the Hewlett-Packard 8970A, is excellent for certain kinds of sensitivity measurements.

## Receiver Sensitivity

Several methods are used to determine receiver sensitivity. The mode under consideration often determines the best choice. One of the most common sensitivity measurements is minimum discernible signal (MDS) or noise floor. It is suitable for CW and SSB receivers.

This measurement indicates the minimum discernible signal that can be detected with the receiver. This level is defined as that which will produce the same audio-output power as the internally generated receiver noise. Hence, the term "noise floor."

To measure MDS, use a signal genera-

tor tuned to the same frequency as the receiver (see Fig 26.56). With the generator output at 0 or with maximum attenuation of its output note the voltmeter reading. Next increase the generator output level until the ac voltmeter at the receiver audio-output jack shows a 3-dB increase. The signal input at this point is the MDS. Be certain that the receiver is peaked on the generator signal. The filter bandwidth can affect the MDS. Always compare MDS readings taken with identical filter bandwidths. (A narrow bandwidth tends to improve MDS performance.) MDS can be expressed in  $\mu\text{V}$  or dBm.

In the hypothetical example of Fig 26.56, the output of the signal generator is  $-133$  dBm and the step attenuator is set to 4 dB. Here is the calculation:

$$\begin{aligned} \text{Noise floor} &= -133 \text{ dBm} - 4 \text{ dB} \\ &= -137 \text{ dBm} \end{aligned} \quad (25)$$

where the noise floor is the power available at the receiver antenna terminal and  $-4$  dB is the loss through the attenuator.

Receiver sensitivity is also often expressed as 10 dB S+N/N (a 10-dB ratio of signal + noise to noise) or 10 dB S/N (signal to noise). The procedure and measurement are identical to MDS, except that the input signal is increased until the receiver output increases by 10 dB for 10 dB S+N/N and 9.5 dB for 10 dB S/N (often called "10 dB signal to noise ratio"). AM receiver sensitivity is usually expressed in this manner with a 30% modulated, 1-kHz test signal. (The modulation in this case is keyed on and off and the signal level is adjusted for the desired increase in the audio output.)

SINAD is a common sensitivity measurement normally associated with FM receivers. It is an acronym for "signal plus noise and distortion." SINAD is a measure of signal quality:

$$\text{SINAD} = \frac{\text{signal} + \text{noise} + \text{distortion}}{\text{noise} + \text{distortion}} \quad (26)$$

where SINAD is expressed in dB. In this

**Fig 26.56 — A general test setup for measuring receiver MDS, or noise floor. Signal levels shown are for an example discussed in the text.**

example, all quantities to the right of the equal sign are expressed in volts, and the ratio is converted to dB by multiplying the log of the fraction by 20.

SINAD(dB)

$$= 20 \log \left( \frac{\text{Signal(V)} + \text{Noise(V)} + \text{Distortion(V)}}{\text{Noise(V)} + \text{Distortion(V)}} \right)$$

Let's look at this more closely. We can consider distortion to be a part of the receiver noise because distortion, like noise, is an unwanted signal added to the desired signal by the receiving system. Then, if we assume that the desired signal is much stronger than the noise, SINAD closely approximates the signal to noise ratio. The common 12-dB SINAD specification therefore corresponds to a 4:1 S/N ratio (noise + distortion =  $0.25 \times$  signal).

The basic test setup for measuring SINAD is shown in Fig 26.57. The level of input signal is adjusted to provide 25% distortion (12 dB SINAD). Narrow-band FM signals, typical for amateur communications, usually have 3-kHz peak deviation when modulated at 1000 Hz.

Noise figure is another measure of receiver sensitivity. It provides a sensitivity evaluation that is independent of the system bandwidth. Noise figure is discussed further in the *Transceivers* chapter.

### Dynamic Range

Dynamic range is the ability of the receiver to tolerate strong signals outside of its band-pass range. Two kinds will be considered:

**Blocking dynamic range** (blocking DR) is the difference, in dB, between the noise floor and a signal that causes 1 dB of gain compression in the receiver. It indicates the signal level, above the noise floor, that begins to cause desensitization.

**IMD dynamic range** (IMD DR) measures the impact of two-tone IMD on a receiver. IMD is the production of spurious responses that results when two or more signals mix. IMD occurs in any receiver when signals of sufficient magnitude are present. IMD DR is the difference, in dB, between the noise floor and the strength of two equal incoming signals that produce a third-order product 3 dB above the noise floor.

What do these measurements mean? When the IMD DR is exceeded, false signals begin to appear along with the desired signal. When the blocking DR is exceeded, the receiver begins losing its ability to amplify weak signals. Typically, the IMD DR is 20 dB or more below the blocking DR, so false signals appear well before sensitivity is significantly decreased. IMD DR is one of the most significant param-

eters that can be specified for a receiver. It is generally a conservative evaluation for other effects, such as blocking, which will occur only for signals well outside the IMD dynamic range of the receiver.

Both dynamic range tests require two signal generators and a hybrid combiner. When testing blocking DR (see Fig 26.58), one generator is set for a weak signal of roughly -110 dBm. The receiver is tuned to this frequency and peaked for maximum response. (ARRL Lab procedures require this level to be about 10 dB below the 1-dB compression point, if the AGC can be disabled. Otherwise, the level is set to 20 dB above the MDS.)

The second generator is set to a frequency 20 kHz away from the first and its level is increased until the receiver output drops by 1 dB, as measured with the ac voltmeter.

In the example shown, the output of the generator is -7 dBm, the loss through the

combiner is fixed at 3 dB and the step attenuator is set to 10 dB. The 1-dB compression level is calculated as follows:

$$\begin{aligned} \text{Blocking level} &= -7 \text{ dBm} - 3 \text{ dBm} - 10 \text{ dB} \\ &= -20 \text{ dBm} \end{aligned} \quad (27)$$

To express this as a dynamic range, the blocking level is referenced to the receiver noise floor (calculated earlier). Calculate it as follows:

$$\begin{aligned} \text{Blocking DR} &= \text{noise floor} - \text{blocking level} \\ &= -137 \text{ dBm} - (-20 \text{ dBm}) \\ &= -117 \text{ dB} \end{aligned} \quad (28)$$

This value is usually expressed as an absolute value: 117 dB.

### Two-Tone IMD Test

The setup for measuring IMD DR is shown in Fig 26.59. Two signals of equal level, spaced 20-kHz apart are injected

Fig 26.57 — FM SINAD test setup.

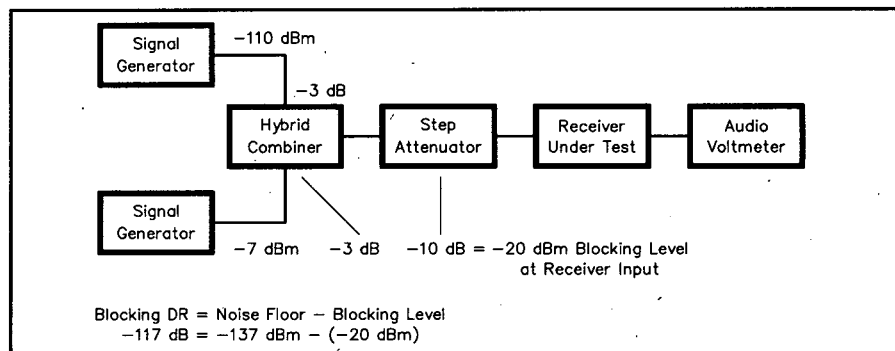

Fig 26.58 — Receiver Blocking DR is measured with this equipment and arrangement. Measurements shown are for the example discussed in the text.

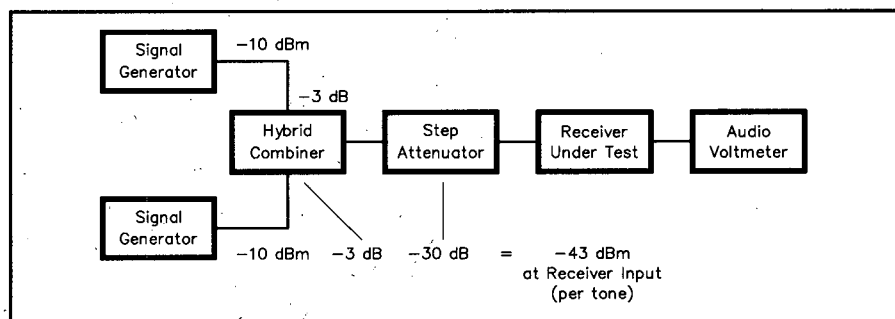

Fig 26.59 — Receiver IMD DR test setup. Signal levels shown are for the example discussed in the text.

into the receiver input. When we call these frequencies  $f_1$  and  $f_2$ , the so-called third-order IMD products will appear at frequencies of  $(2f_1 - f_2)$  and  $(2f_2 - f_1)$ . If the two input frequencies are 14.040 and 14.060 MHz, the third-order products will be at 14.020 and 14.080 MHz. Let's talk through a measurement with these frequencies.

First, set the generators for  $f_1$  and  $f_2$ . Adjust each of them for an output of  $-10$  dBm. Tune the receiver to either of the third-order IMD products. Adjust the step attenuator until the IMD product produces an output 3 dB above the noise level as read on the ac voltmeter.

For an example, say the output of the generator is  $-10$  dBm, the loss through the combiner is 3 dB and the amount of attenuation used is 30 dB. The signal level at the receiver antenna terminal that just begins to cause IMD problems is calculated as:

$$\begin{aligned}\text{IMD level} &= -10 \text{ dBm} - 3 \text{ dB} - 30 \text{ dB} \\ &= -43 \text{ dBm}\end{aligned}\quad (29)$$

To express this as a dynamic range the IMD level is referenced to the noise floor as follows:

$$\begin{aligned}\text{IMD DR} &= \text{noise floor} - \text{IMD level} \quad (30) \\ &= -137 \text{ dBm} - (-43 \text{ dBm}) \\ &= -94 \text{ dB}\end{aligned}$$

Therefore, the IMD dynamic range of this receiver would be 94 dB.

### Third-Order Intercept

Another parameter used to quantify receiver performance is the third-order input intercept ( $IP^3$ ). This is the point at which the desired response and the third-order IMD response intersect, if extended beyond their linear regions (see Fig 26.60). Greater  $IP^3$  indicates better

**Fig 26.60** — A plot of the receiver characteristics that determine third-order input intercept, a measure of receiver performance.

**Fig 26.61** — Performance plot of the receiver discussed in the text. This is a good way to visualize the interaction of receiver-performance measurements.

receiver performance. Calculate  $IP^3$  like this:

$$IP^3 = 1.5 (\text{IMD dynamic range in dB}) + (\text{MDS in dBm}) \quad (31)$$

For our example receiver:

$$IP^3 = 1.5 (94 \text{ dB}) + (-137 \text{ dBm}) = +4 \text{ dBm}$$

The example receiver we have discussed here is purely imaginary. Nonetheless, its performance is typical of contemporary communications receivers.

### Evaluating the Data

Thus far, a fair amount of data has been gathered with no mention of what the numbers really mean. It is somewhat easier to understand exactly what is happening by arranging the data as shown in Fig 26.61. The base line represents power levels with a very small level at the left and a higher level (0 dBm) at the right.

The noise floor of our hypothetical receiver is at  $-137$  dBm, the IMD level (the level at which signals will begin to create spurious responses) at  $-43$  dBm and the blocking level (the level at which signals will begin to desensitize the receiver) at  $-20$  dBm. The IMD dynamic range is some 23 dB smaller than the blocking dynamic range. This means IMD products will be heard long before the receiver begins to desensitize, some 23 dB sooner.

### SPECTRUM ANALYZERS

A spectrum analyzer is similar to an oscilloscope. Both visually present an electrical signal through graphic representation. The oscilloscope is used to observe electrical signals in the time domain (amplitude as a function of time). The time domain, however, gives little information about the frequencies that make up complex signals. Amplifiers, mixers, oscillators, detectors, modulators and filters are best characterized in terms of their frequency response. This information is obtained by viewing electrical signals in the frequency domain (amplitude as a func-

**Fig 26.62** — A complex signal in the time and frequency domains. A is a three-dimensional display of amplitude, time and frequency. B is an oscilloscope display of time vs amplitude. C is spectrum analyzer display of the frequency domain and shows frequency vs amplitude.

tion of frequency). One instrument that can display the frequency domain is the spectrum analyzer.

### Time and Frequency Domain

To better understand the concepts of time and frequency domain, see Fig 26.62. The three-dimensional coordinates show time (as the line sloping toward the bottom right), frequency (as the line rising toward the top right) and amplitude (as the vertical axis). The two discrete frequencies shown are harmonically related, so we'll refer to them as  $f_1$  and  $2f_1$ .

In the representation of time domain at B, all frequency components of a signal are summed together. In fact, if the two discrete frequencies shown were applied to the input of an oscilloscope, we would see the solid line (which corresponds to  $f_1 + 2f_1$ ) on the display.

In the frequency domain, complex signals (signals composed of more than one

frequency) are separated into their individual frequency components. A spectrum analyzer measures and displays the power level at each discrete frequency; this display is shown at C.

The frequency domain contains information not apparent in the time domain and therefore the spectrum analyzer offers advantages over the oscilloscope for certain measurements. As might be expected, some measurements are best made in the time domain. In these cases, the oscilloscope is a valuable instrument.

### Spectrum Analyzer Basics

There are several different types of spectrum analyzers, but by far the most common is nothing more than an electronically tuned superheterodyne receiver. The receiver is tuned by means of a ramp voltage. This ramp voltage performs two functions: First, it sweeps the frequency of the analyzer local oscillator; second, it deflects a beam across the horizontal axis of a CRT display, as shown in Fig 26.63. The vertical axis deflection of the CRT beam is determined by the strength of the received signal. In this way, the CRT displays frequency on the horizontal axis and signal strength on the vertical axis.

Most spectrum analyzers use an up-converting technique so that a fixed tuned input filter can remove the image. Only the first local oscillator need be tuned to tune the receiver. In the up-conversion design, a wide-band input is converted to

an IF higher than the highest input frequency. As with most up-converting communications receivers, it is not easy to achieve the desired ultimate selectivity at the first IF, because of the high frequency. For this reason, multiple conversions are used to generate an IF low enough so that the desired selectivity is practical. In the example shown, dual conversion is used: The first IF is at 400 MHz; the second at 10.7 MHz.

In the example spectrum analyzer, the first local oscillator is swept from 400 MHz to 700 MHz; this converts the input (from nearly 0 MHz to 300 MHz) to the first IF of 400 MHz. The usual rule of thumb for varactor tuned oscillators is that the maximum practical tuning ratio (the ratio of the highest frequency to the lowest frequency) is an octave, a 2:1 ratio. In our example spectrum analyzer, the tuning ratio of the first local oscillator is 1.75:1, which meets this specification.

The image frequency spans 800 MHz to 1100 MHz and is easily eliminated using a low-pass filter with a cut-off frequency around 300 MHz. The 400-MHz first IF is converted to 10.7 MHz where the ultimate selectivity of the analyzer is obtained. The image of the second conversion, (421.4 MHz), is eliminated by the first IF filter. The attenuation of the image should be great, on the order of 60 to 80 dB. This requires a first IF filter with a high Q; this is achieved by using helical resonators, SAW resonators or

cavity filters. Another method of eliminating the image problem is to use triple conversion; converting first to an intermediate IF such as 50 MHz and then to 10.7 MHz. As with any receiver, an additional frequency conversion requires added circuitry and adds potential spurious responses.

Most of the signal amplification takes place at the lowest IF; in the case of the example analyzer this is 10.7 MHz. Here the communications receiver and the spectrum analyzer differ. A communications receiver demodulates the incoming signal so that the modulation can be heard or further demodulated for RTTY or packet or other mode of operation. In the spectrum analyzer, only the signal strength is needed.

In order for the spectrum analyzer to be most useful, it should display signals of widely different levels. As an example, signals differing by 60 dB, which is a thousand to one difference in voltage or a million to one in power, would be difficult to display. This would mean that if power were displayed, one signal would be one million times larger than the other (in the case of voltage one signal would be a thousand times larger). In either case it would be difficult to display both signals on a CRT. The solution to this problem is to use a logarithmic display that shows the relative signal levels in decibels. Using this technique, a 1000:1 ratio of voltage reduces to a 60-dB difference.

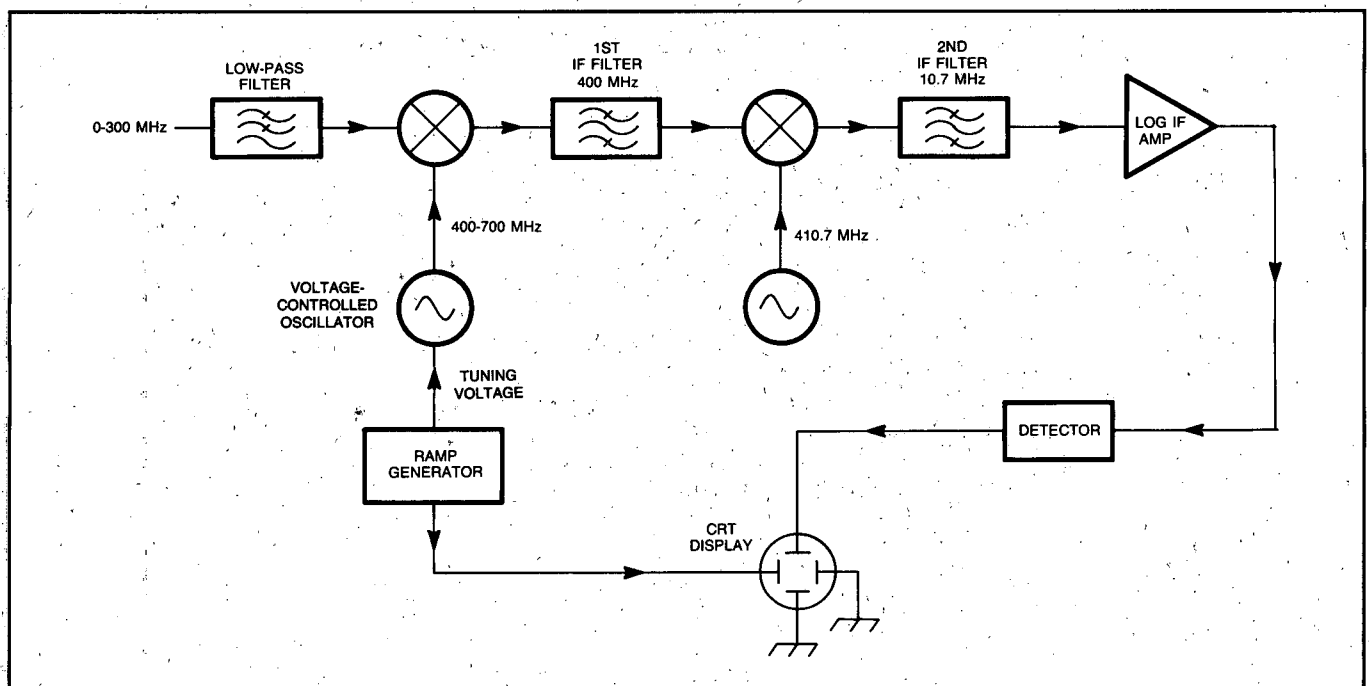

Fig 26.63 — A block diagram of a superheterodyne spectrum analyzer. Input frequencies of up to 300 MHz are up converted by the local oscillator and mixer to a fixed frequency of 400 MHz.

The conversion of the signal to a logarithm is usually performed in the IF amplifier or detector, resulting in an output voltage proportional to the logarithm of the input RF level. This output voltage is then used to drive the CRT display.

### **Spectrum Analyzer Performance Specifications**

The performance parameters of a spectrum analyzer are specified in terms similar to those used for radio receivers, in spite of the fact that there are many differences between a receiver and a spectrum analyzer.

The sensitivity of a receiver is often specified as the minimum discernible signal, which means the smallest signal that can be heard. In the case of the spectrum analyzer, it is not the smallest signal that can be heard, but the smallest signal that can be seen. The dynamic range of the spectrum analyzer determines the largest and smallest signals that can be simultaneously viewed on the analyzer. As with a receiver, there are several factors that can affect dynamic range, such as IMD, second- and third-order distortion and blocking. IMD dynamic range is the maximum difference in signal level between the minimum detectable signal and the level of two signals of equal strength that generate an IMD product equal to the minimum detectable signal.

Although the communications receiver is an excellent example to introduce the spectrum analyzer, there are several differences such as the previously explained lack of a demodulator. Unlike the communications receiver, the spectrum analyzer is not a sensitive radio receiver. To preserve a wide dynamic range, the spectrum analyzer often uses passive mixers for the

first and second mixers. Therefore, referring to Fig 26.63, the noise figure of the analyzer is no better than the losses of the input low-pass filter plus the first mixer, the first IF filter, the second mixer and the loss of the second IF filter. This often results in a combined noise figure of more than 20 dB. With that kind of noise figure the spectrum analyzer is obviously not a communications receiver for extracting very weak signals from the noise but a measuring instrument for the analysis of frequency spectrum.

The selectivity of the analyzer is called the resolution bandwidth. This term refers to the minimum frequency separation of two signals of equal level that can be resolved so there is a 3-dB dip between the two. The IF filters used in a spectrum analyzer differ from a communications receiver in that the filters in a spectrum analyzer have very gentle skirts and rounded passbands, rather than the flat passband and very steep skirts used on an IF filter in a high-quality communications receiver. This rounded passband is necessary because the signals pass into the filter passband as the spectrum analyzer scans the desired frequency range. If the signals suddenly pop into the passband (as they would if the filter had steep skirts), the filter tends to ring; a filter with gentle skirts is less likely to ring. This ringing, called scan loss, distorts the display and requires that the analyzer not sweep frequency too quickly. All this means that the scan rate must be checked periodically to be certain the signal amplitude is not affected by fast tuning.

### **Spectrum Analyzer Applications**

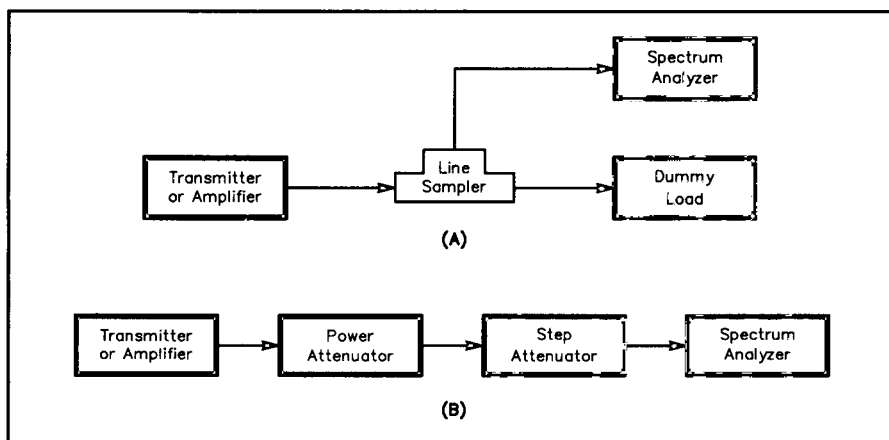

Spectrum analyzers are used in situations where the signals to be analyzed are

very complex and an oscilloscope display would be an indecipherable jumble. The spectrum analyzer is also used when the frequency of the signals to be analyzed is very high. Although high-performance oscilloscopes are capable of operation into the UHF region, moderately priced spectrum analyzers can be used well into the gigahertz region.

A spectrum analyzer can also be used to view very low-level signals. For an oscilloscope to display a VHF waveform, the bandwidth of the oscilloscope must extend from zero to the frequency of the waveform. If harmonic distortion and other higher-frequency distortions are to be seen the bandwidth of the oscilloscope must exceed the fundamental frequency of the waveform. This broad bandwidth can also admit a lot of noise power. The spectrum analyzer, on the other hand, analyzes the waveform using a narrow bandwidth; thus it is capable of reducing the noise power admitted.

Probably the most common application of the spectrum analyzer is the measurement of the harmonic content and other spurious signals in the output of a radio transmitter. Fig 26.64 shows two ways to connect the transmitter and spectrum analyzer. The method shown at A should not be used for wide-band measurements since most line-sampling devices do not exhibit a constant-amplitude output over a broad frequency range. Using a line sampler is fine for narrow-band measurements, however. The method shown at B is used in the ARRL Lab. The attenuator must be capable of dissipating the transmitter power. It must also have sufficient attenuation to protect the spectrum analyzer input. Many spectrum analyzer mixers can be damaged by only a few milliwatts, so most analyzers have an adjustable input attenuator that will provide a reasonable amount of attenuation to protect the sensitive input mixer from damage. The power limitation of the attenuator itself is usually on the order of a watt or so, however. This means that 20 dB of additional attenuation is required for a 100-W transmitter, 30 dB for a 1000-W transmitter and so on, to limit the input to the spectrum analyzer to 1 W. There are specialized attenuators that are made for transmitter testing; these attenuators provide the necessary power dissipation and attenuation in the 20 to 30-dB range.

When using a spectrum analyzer it is very important that the maximum amount of attenuation be applied before a measurement is made. In addition, it is a good practice to start with maximum attenuation and view the entire spectrum of a signal before the attenuator is adjusted. The signal being viewed could appear to be at

**Fig 26.64 — Alternate bench setups for viewing the output of a high power transmitter or oscillator on a spectrum analyzer. A uses a line sampler to pick off a small amount of the transmitter or amplifier power. In B, most of the transmitter power is dissipated in the power attenuator.**

a safe level, but another spectral component, which is not visible, could be above the damage limit. It is also very important to limit the input power to the analyzer when pulse power is being measured. The average power may be small enough so the input attenuator is not damaged, but the peak pulse power, which may not be readily visible on the analyzer display, can destroy a mixer, literally in microseconds.

When using a spectrum analyzer it is necessary to ensure that the analyzer does not generate additional spurious signals that are then attributed to the system under test. Some of the spurious signals that can be generated by a spectrum analyzer are harmonics and IMD. If it is desired to measure the harmonic levels of a transmitter at a level below the spurious level of the analyzer itself, a notch filter can be inserted between the attenuator and the spectrum analyzer as shown in Fig 26.65. This reduces the level of the fundamental signal and prevents that signal from generating harmonics within the analyzer, while still allowing the harmonics from the transmitter to pass through to the analyzer without attenuation. Use caution with this technique; detuning the notch filter or inadvertently changing the transmitter frequency will allow potentially high levels of power to enter the analyzer. In addition, use care when choosing filters; some filters (such as cavity filters) respond not only to the fundamental but notch out odd harmonics as well.

It is good practice to check for the generation of spurious signals within the spectrum analyzer. When a spurious signal is generated by a spectrum analyzer, adding attenuation at the analyzer input will cause the internally generated spurious signals to decrease by an amount greater than the added attenuation. If attenuation added ahead of the analyzer causes all of the visible signals to decrease by the same amount, this indicates a spurious-free display.

The input impedance for most RF spectrum analyzers is 50  $\Omega$ ; not all circuits have convenient 50- $\Omega$  connections that can be accessed for testing purposes, however. Using a probe such as the one shown in Fig 26.66 allows the analyzer to be used as a troubleshooting tool. The probe can be used to track down signals within a transmitter or receiver, much like an oscilloscope is used. The probe shown offers a 100:1 voltage reduction and loads the circuit with 5000  $\Omega$ . A different type of probe is shown in Fig 26.67. This inductive pickup coil (sometimes called a "sniffer") is very handy for troubleshooting. The coil is used to couple signals from the radiated magnetic field of a circuit into

**Fig 26.65** — A notch filter is another way to reduce the level of a transmitter's fundamental signal so that the fundamental does not generate harmonics within the analyzer. However in order to know the amplitude relationship between the fundamental and the transmitter's actual harmonics and spurs the attenuation of the fundamental in the notch filter must be known.

**Fig 26.66** — A voltage probe designed for use with a spectrum analyzer. Keep the probe tip (resistor and capacitor) and ground leads as short as possible.

the analyzer. A short length of miniature coax is wound into a pick-up loop and soldered to a larger piece of coax. The use of the coax shields the loop from coupling energy from the electric field component. The dimensions of the loop are not critical, but smaller loop dimensions make the loop more accurate in locating the source of radiated RF. The shield of the coax provides a complete electrostatic shield without introducing a shorted turn.

The sniffer allows the spectrum analyzer to sense RF energy without contacting the circuit being analyzed. If the loop is brought near an oscillator coil, the oscillator can be tuned without directly contacting (and thus disturbing) the circuit. The oscillator can then be checked for reliable starting and the generation of spurious sidebands. With the coil brought near the tuned circuits of amplifiers or frequency multipliers, those stages can be tuned using a similar technique.

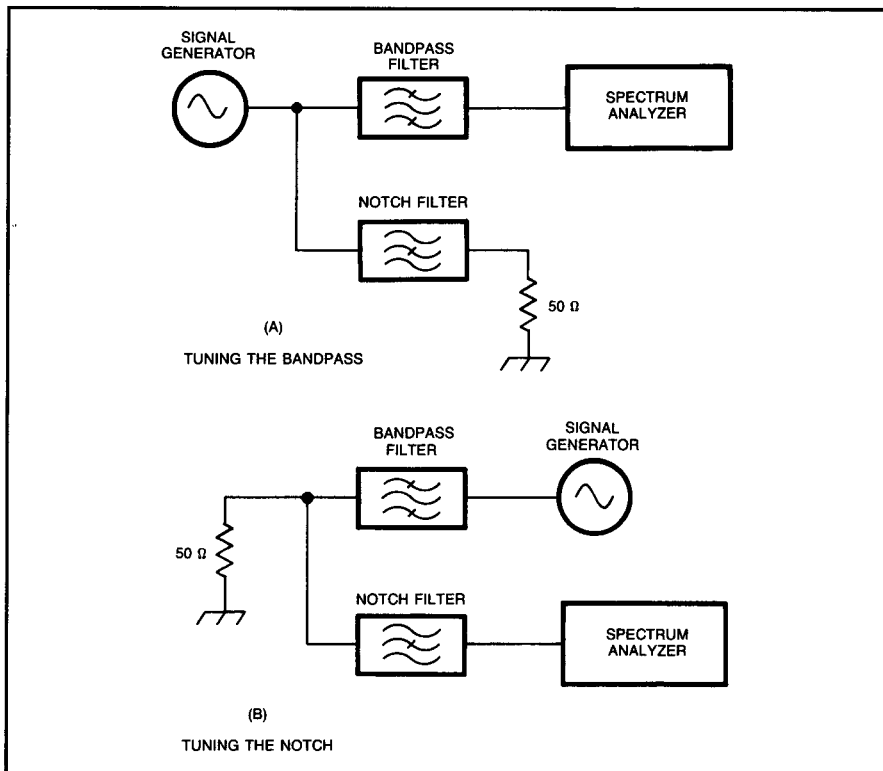

Even though the sniffer does not contact the circuit being evaluated, it does extract some energy from the circuit. For this reason, the loop should be placed as far from the tuned circuit as is practical. If

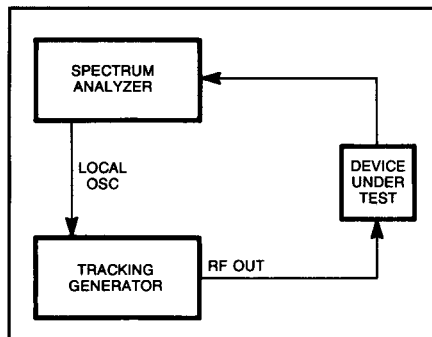

**Fig 26.67** — A "sniffer" probe consisting of an inductive pick-up. It has an advantage of not loading the circuit under test. See text for details.

the loop is placed too far from the circuit, the signal will be too weak or the pick-up loop will pick up energy from other parts of the circuit and not give an accurate indication of the circuit under test.

The sniffer is very handy to locate sources of RF leakage. By probing the shields and cabinets of RF-generating equipment (such as transmitters) egress and ingress points of RF energy can be identified by increased indications on the analyzer display.

**Fig 26.68 — Block diagram of a spectrum analyzer and signal generator being used to tune the band-pass and notch filters of a duplexer. All ports of the duplexer must be properly terminated and good quality coax with intact shielding used to reduce leakage.**

**Fig 26.69 — A signal generator (shown in the figure as the "Tracking Generator") locked to the local oscillator of a spectrum analyzer can be used to determine filter response over a range of frequencies.**

One very powerful characteristic of the spectrum analyzer is the instrument's capability to measure very low-level signals. This characteristic is very advantageous when very high levels of attenuation are measured. **Fig 26.68** shows the setup for tuning the notch and passband of a VHF duplexer. The spectrum analyzer, being capable of viewing signals well into the low microvolt region, is capable of measuring the insertion loss of the notch cavity more than 100 dB below the signal genera-

**Fig 26.70 — A network analyzer is usually found in commercial communications development labs. It can measure both the phase and magnitude of the filter input and output signals. See text for details.**

tor output. Making a measurement of this sort requires care in the interconnection of the equipment and a well designed spectrum analyzer and signal generator. RF energy leaking from the signal generator cabinet, line cord or even the coax itself, can get into the spectrum analyzer through similar paths and corrupt the measurement. This leakage can make the measurement look either better or worse than the actual attenuation, depending on the phase relationship of the leaked signal.

## Extensions of Spectral Analysis

What if a signal generator is connected to a spectrum analyzer so that the signal generator output frequency is exactly the same as the receiving frequency of the spectrum analyzer? It would certainly appear to be a real convenience not to have to continually reset the signal generator to the desired frequency. It is, however, more than a convenience. A signal generator connected in this way is called a tracking generator because the output frequency tracks the spectrum analyzer input frequency. The tracking generator makes it possible to make swept frequency measurements of the attenuation characteristics of circuits, even when the attenuation involved is large.

**Fig 26.69** shows the connection of a tracking generator to a circuit under test. In order for the tracking generator to create an output frequency exactly equal to the input frequency of the spectrum analyzer, the internal local oscillator frequencies of the spectrum analyzer must be known. This is the reason for the interconnections between the tracking generator and the spectrum analyzer. The test setup shown will measure the gain or loss of the circuit under test. Only the magnitude of the gain or loss is available; in some cases, the phase angle between the input and output would also be an important and necessary parameter.

The spectrum analyzer is not sensitive to the phase angle of the tracking generator output. In the process of generating the tracking generator output, there are no guarantees that the phase of the tracking generator will be either known or constant. This is especially true of VHF spectrum analyzers/tracking generators where a few inches of coaxial cable represents a significant phase shift.

One effective way of measuring the phase angle between the input and output of a device under test is to sample the phase of the input and output of device under test and apply the samples to a phase detector. **Fig 26.70** shows a block diagram of this technique. An instrument that can measure both the magnitude and phase of a signal is called a vector network analyzer or simply a network analyzer. The magnitude and phase can be displayed either separately or together. When the magnitude and phase are displayed together the two can be presented as two separate traces, similar to the two traces on a dual-trace oscilloscope. A much more useful method of display is to present the magnitude and phase as a polar plot where the locus of the points of a vector having the length of the magnitude and the angle of the phase are displayed. Very sophisticated network analyzers can display all of the S parameters of a circuit in either a polar format or a Smith Chart format.

# Transmitter Performance Tests

The test setup used in the ARRL Laboratory for measuring an HF transmitter or amplifier is shown in Fig 26.71. As can be seen, different power levels dictate different amounts of attenuation between the transmitter or amplifier and the spectrum analyzer.

## Spurious Emissions

Fig 26.72 shows the broadband spectrum of a transmitter, showing the harmonics in the output. The horizontal (frequency) scale is 5 MHz per division; the main output of the transmitter at 7 MHz can be seen about 1.5 major divisions from the left of the trace. A very large apparent signal is seen at the extreme left of the trace. This occurs at what would be zero frequency and it is caused by the first local oscillator frequency being exactly the first

IF. All up-converting superheterodyne spectrum analyzers have this IF feedthrough; in addition, this signal is occasionally accompanied by a smaller spurious signal; generated within the analyzer. To determine what part of the displayed signal is a spurious response caused by IF feedthrough and what is an actual input signal, simply remove the input signal and observe the trace. It is not necessary or desirable that the transmitter be modulated for this broadband test.

Other transmitter tests that can be performed with a spectrum analyzer include measurement of two-tone IMD and SSB carrier and unwanted sideband suppression.

## Two-Tone IMD

Investigating the sidebands from a modulated transmitter requires a narrow-

band spectrum analysis and produces displays similar to that shown in Fig 26.73. In this example, a two-tone test signal is used to modulate the transmitter. The display shows the two test tones plus some of the IMD produced by the SSB transmitter. The test setup used to produce this display is shown in Fig 26.74.

In this example, a two-tone test signal with frequencies of 700 and 1900 Hz is used to modulate the transmitter. Set the transmitter output and audio input to the manufacturer's specifications. Each desired tone is adjusted to be equal in amplitude and centered on the display. The step attenuators and analyzer controls are then adjusted to set the two desired signals 6 dB below the 0-dB reference (top) line. The IMD products can then be read directly from the display in terms of "dB below Peak Envelope Power (PEP)." (In the example shown, the third-order products are 30 dB below PEP, the fifth-order products are 37 dB down, the seventh-order products are down 44 dB.)

## Carrier and Unwanted Sideband Suppression

Single-tone audio input signals can be used with the same setup to measure unwanted sideband and carrier suppression of SSB signals. In this case, set the single tone to the 0-dB reference line. (Once the level is set, the audio can be disabled for carrier suppression measurements in order to eliminate IMD and other effects.)

## Phase Noise

Phase/composite noise is also measured with spectrum analyzers in the ARRL Lab.

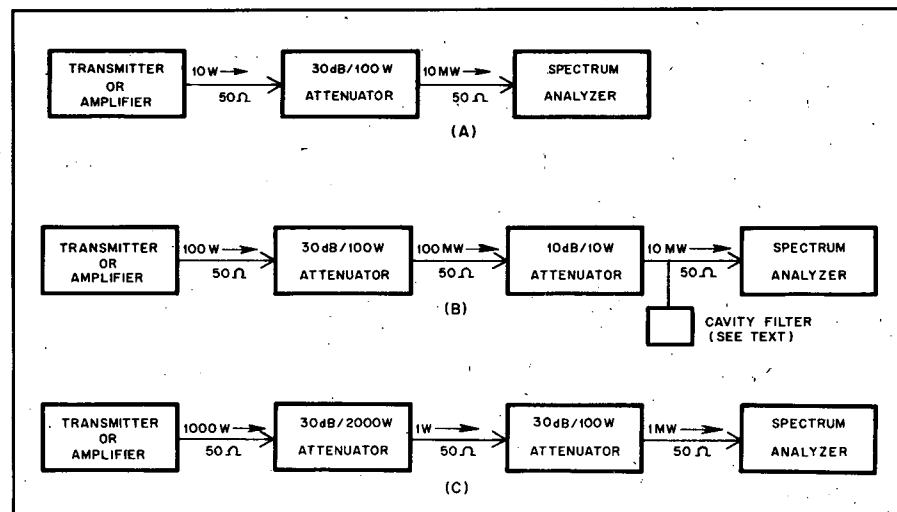

Fig 26.71 — These setups are used in the ARRL Laboratory for testing transmitters or amplifiers with several different power levels.

Fig 26.72 — Comparison of two different transmitters on the 40-m band as seen on a spectrum analyzer display. The photograph at A shows a relatively clean transmitted signal but the transmitter at B shows more spurious signal content. Horizontal scale is 5 MHz per division; vertical is 10 dB per division. According to current FCC spectral purity requirements both transmitters are acceptable.

Fig 26.73 — An SSB transmitter two-tone test as seen on a spectrum analyzer. Each horizontal division represents 1 kHz and each vertical division is 10 dB. The third-order products are 30 dB below the PEP (top line), the fifth-order products are down 37 dB and seventh-order products are down 44 dB. This represents acceptable (but not ideal) performance.

This test requires specialized equipment and is included here for information purposes only.

The purpose of the Composite-Noise test is to observe and measure the phase and amplitude noise, as well as any close-in spurious signals generated by a transmitter. Since phase noise is the primary noise component in any well-designed transmitter, almost all of the noise observed during this test is phase noise.

This measurement is accomplished in the lab by converting the transmitter output down to a frequency about 10 or 20 kHz above baseband. A mixer and a signal generator (used as a local oscillator)

are used to perform this conversion. Filters remove the 0-Hz component as well as any unwanted heterodyne components. A spectrum analyzer (see Fig 26.75) displays the remaining noise and spurious signals from 2 to 20 kHz from the carrier frequency (in the CW mode).

### Tests in the Time Domain

Oscilloscopes are used for transmitter testing in the time domain. Dual-trace instruments are best in most cases, providing easy to read time-delay measurements between keying input and RF- or audio-output signals. Common transmitter measurements performed with 'scopes include

CW keying wave shape and time delay and SSB/FM transmit-to-audio turnaround tests (important for many digital modes).

A typical setup for measuring CW keying waveform and time delay is shown in Fig 26.76. A keying test generator is used to repeatedly key the transmitter at a controlled rate. The generator can be set to any reasonable speed, but ARRL tests are usually conducted at 20-ms on and 20-ms off (25 Hz, 50% duty cycle). Fig 26.77 shows a typical display. The rise and fall times of the RF output pulse are measured between the 10% and 90% points on the leading and trailing edges, respectively. The delay times are measured between the 50% points of the keying and RF output waveforms. Look at the **Transceivers** chapter for further discussion of CW keying issues.

For voice modes (SSB/FM), a PTT-to-RF output test is similar to CW keying tests. It measures rise and fall times, as well as the on- and off-delay times just as in the CW test. See Fig 26.78 for the test setup.

"Turn-around time" is the time it takes for a transceiver to switch from the 50% fall time of a keying pulse to 50% rise of audio output. The test setup is shown in Fig 26.79. Turn-around time measurements require extreme care with respect to transmitter output power, attenuation, signal-generator output and the maximum input signal that can be tolerated by the generator. The generator's specifications must not be exceeded and the input to the receiver must be at the required level, usually S9. Receiver AGC is usually off for this test, but experimentation with AGC and signal input level can reveal surprising variations. The keying rate must be

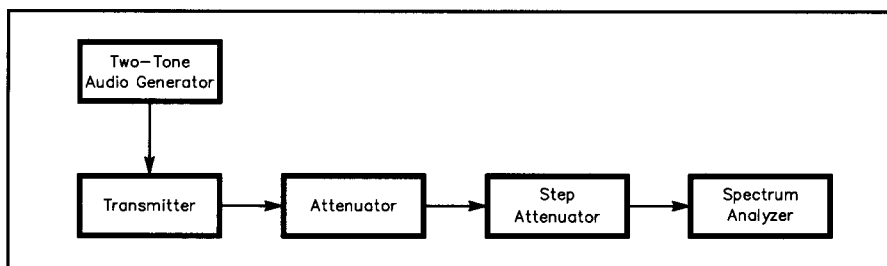

Fig 26.74 — The test setup used in the ARRL Laboratory to measure the IMD performance of transmitters and amplifiers.

Fig 26.75 — The spectral-display results of a composite-noise test in the ARRL Lab. This display is for the ICOM IC-707 reviewed in April 94 QST. Power output is 100 W at 14 MHz. Vertical divisions are 10 dB; horizontal divisions are 2 kHz. The log reference level (the top horizontal line on the scale) represents -60 dBc/Hz and the baseline is -140 dBc/Hz. The carrier, off the left edge of the plot, is not shown. This plot shows composite transmitted noise 2 to 20 kHz from the carrier.

Fig 26.76 — CW keying waveform test setup.

Fig 26.77 — Typical CW keying waveform test results. This display is for the ICOM IC-707 (semi-break-in mode) reviewed in April 94 QST. The upper trace is the actual key closure; the lower trace is the RF envelope. Horizontal divisions are 10 ms. The transceiver was being operated at 100 W output at 14 MHz.

considerably slower than the turn-around time; rates of 200-ms on/200-ms off or faster, have been used with success in Product Review tests at the ARRL Lab.

Turn-around time is an important consideration with some digital modes. AMTOR, for example, requires a turn-around time of 35 ms or less.

## GLOSSARY

**AC** (Alternating current) — The polarity constantly reverses, as contrasted to dc (direct current) where polarity is fixed.

**Analog** — Signals which have a full set of values. If the signal varies between 0 and 10 V all values in this range can be found. Compare this to a *digital* system.

**Attenuator** — A device which reduces the amplitude of a signal

**Average value** — Obtained by recording or measuring  $N$  samples of a signal, adding up all of these values, and dividing this sum by  $N$ .

**Bandwidth** — A measure of how wide a signal is in frequency. If a signal covers 14,200 to 14,205 kHz its bandwidth is said to be 5 kHz.

**BNC** — A small connector used with coax cable.

**Bridge circuit** — Four passive elements, such as resistors, inductors, connected as a pair of voltage dividers with a meter or other measuring device across two opposite junctions. Used to indicate the relative values of the four passive elements. See the chapter discussion of Wheatstone bridges.

**CMOS** — A family of digital logic elements usually selected for their low power drain. See **Digital** chapter of this *Handbook*.

**Coaxial cable (coax)** — A cable formed of two conductors that share the same axis. The center conductor may be a single wire or a stranded cable. The outer conductor is called the shield. The shield may be flexible braid, foil, semi-rigid or rigid metal. For more information, look in the **Transmission Lines** chapter.

**Combiners** — See *Hybrid*.

**D'Arsonval meter** — A common mechanical meter consisting of a permanent magnet and a moving coil (with pointer attached).

**DC** (direct current) — The polarity is fixed for all time, as contrasted to ac (alternating current) where polarity constantly reverses.

**Digital** — A system that allows signals to assume a finite range of states. Binary logic is the most common example. Only two values are permitted in a binary system: one value is defined as a

logical 1 and the other value as a logical 0. See the *Handbook* chapter on **Digital Systems**.

**Divider** — A network of components that produce an output signal that is a fraction of the input signal. The ratio of the output to the input is the division factor. An analog divider divides voltage (a string of series connected resistors) or current (parallel connected resistors). Digital dividers divide pulse trains or frequency.

**DMM (Digital multimeter)** — A test instrument that usually measures at least: voltage, current and resistance, and displays the result on a numeric digit display, rather than an analog meter.

**Dummy antenna or dummy load** — A resistor or set of resistors used in place of an antenna to test a transmitter without radiating any electromagnetic energy into the air.

**DVM (digital volt meter)** — See *DMM*.

**FET voltmeter** — See also *VTVM*. An updated version of a VTVM using field effect transistors (FETs) in place of vacuum tubes.

**Flip-flop** — A digital circuit that has two stable states. See the chapter on **Digital Techniques**.

**Frequency marker** — Test signals generated at selected intervals (such as 25 kHz, 50 kHz, 100 kHz) for calibrating the dials of receivers and transmitters.

**Fundamental** — The first signal or frequency in a series of harmonically related signals. This term is often used to describe an oscillator or transmitter's desired signal.

**Harmonic** — A signal occurring at some integral multiple (such as two, three, four) of a *fundamental* frequency.

**Hybrid (hybrid combiners)** — A device used to connect two signal generators to one receiver for test purposes, without the two generators affecting each other.

**IC (integrated circuit)** — A complete circuit built into a single electronic component.

**LCD (liquid crystal display)** — A low-power display device utilizing the physics of liquid crystals. They usually need either ambient light or backlighting to be seen.

**LED (light emitting diode)** — A diode that emits light when an appropriate voltage (usually 1.5 V at about 20 mA) is connected. They are used either as tiny pilot lights or in bar shapes to display letters and numbers.

**Loran** — A navigation system using very-low-frequency transmitters.

**Marker** — See *Frequency marker*.

**Multiplier** — A circuit that purposely creates some desired *harmonic* of its input signal. For example, a frequency multiplier that takes energy from a 3.5-MHz exciter and puts out RF at 7 MHz is a two times multiplier, usually called a frequency doubler.

**N** — A type of coaxial cable connector common at UHF and higher frequencies.

**NAND** — A digital element that performs the *not-and* function. See the **Digital** chapter.

**Noise (noise figure)** — Noise is gener-

ated in all electrical circuits. It is particularly critical in those stages of a receiver that are closest to the antenna (RF amplifier and mixer), because noise generated in these stages can mask a weak signal. The noise figure is a measure of this noise generation. Lower noise figures mean that less noise is generated and weaker signals can be heard.

**NOR** — A digital element that performs the *not-or* function. See the **Digital** chapter.

**Null (nulling)** — The process of adjusting a circuit for a minimum reading on a test meter or instrument. At a perfect null there is null, or no, energy to be seen.

**Ohmmeter** — A meter that measures the value of resistors. Usually part of a multimeter. See *VOM* and *DMM*.

**Peak value** — The highest value of a signal during the measuring time. If a measured voltage varies in value from 1 to 10 V over a measuring period, the peak value would be the highest measured, 10 V.

**PL-259** — A connector used for coaxial cable, usually at HF. It is also known as a male UHF connector. It is an inexpensive and common connector, but it is not weatherproof, nor is its impedance constant over frequency.

**Prescaler** — A circuit used ahead of a counter to extend the counter range to higher frequencies. A counter capable of operating up to 50 MHz can count up to 500 MHz when used with a  $\times 10$  prescaler.

**Q** — The ratio of the reactance to the resistance of a component or circuit. It provides a measure of bandwidth. Lower resistive losses make for a higher Q, and a narrower bandwidth.

**RMS (root mean square)** — A measure of the value of a voltage or current obtained by taking values from successive small time slices over a complete cycle of the wave form, squaring those values, taking the mean of the squares, and then the square root of the mean. Very significant when working with good ac

sine waves, where the RMS of the sine wave is 0.707 of the peak value.

**Scope** — Slang for oscilloscope. See the Oscilloscope section of this chapter.

**Shunt** — Elements connected in parallel.

**Sinusoidal (sine wave)** — The nominal waveform for unmodulated RF energy and many other ac voltages.

**Spectrum** — Used to describe a range of frequencies or wavelengths. The RF spectrum starts at perhaps 10 kHz and extends up to several hundred gigahertz. The light spectrum goes from infrared to ultraviolet.

**Spurious emissions, or spurs** — Unwanted energy generated by a transmitter or other circuit. These emissions include, but are not limited to, *harmonics*.

**Thermocouple** — A device made up of two different metals joined at two places. If one joint is hot and the other cold a voltage may be developed, which is a measure of the temperature difference.

**Time domain** — A measurement technique where the results are plotted or shown against a scale of time. In contrast to the frequency domain, where the results are plotted against a scale of frequency.

**TTL (Transistor-transistor-logic)** — A logic IC family commonly used with 5 V supplies. See the chapter on **Digital Techniques**.

**Vernier dial or vernier drive** — A mechanical system of tuning dials, frequently used in older equipment, where the knob might turn 10 times for each single rotation of the control shaft.

**VOM (volt-ohm-meter)** — A multimeter whose design predates multiple scale meters (see *DMM*).

**VTVM (vacuum tube voltmeter)** — A meter that was developed to provide a high input resistance and therefore low current drain (loading) from the circuit being tested. Now replaced by the FET meter.

**Wheatstone bridge** — See *Bridge circuit*.

# Troubleshooting and Repair

Traditionally, the radio amateur has maintained a working knowledge of electronic equipment. This knowledge, and the ability to make repairs with whatever resources are available, keeps amateur stations operating when all other communications fail. This troubleshooting ability is not only a tradition; it is fundamental to the existence of the service.

This chapter, by Ed Hare, KA1CV, tells you what to do when you are faced with equipment failure or a circuit that doesn't work. It will help you ask and answer the right questions: "Should I fix it or send it back to the dealer for repair? What do I need to know to be able to fix it myself? Where do I start? What kind of test equipment do I need?" The best answers to these questions will depend on the type of test equipment you have available, the availability of a schematic or service manual and the depth of your own electronic and troubleshooting experience.

Not everyone is an electronics wizard; your set may end up at the repair shop in spite of your best efforts. The theory you learned for the FCC examinations and the information in this *Handbook* can help you decide if you can fix it yourself. If the problem is something simple (and most are), why not avoid the effort of shipping the radio to the manufacturer? It is gratifying to save time and money, but, even better, the experience and confidence you gain by fixing it yourself may prove even more valuable.

Although some say troubleshooting is as much art as it is science, the repair of electronic gear is not magic. It is more like detective work. A knowledge of complex

math is not required. However, you must have, or develop, the ability to read a schematic diagram and to visualize signal flow through the circuit.

## SAFETY FIRST

Always! Death is permanent. A review of safety must be the first thing discussed in a troubleshooting chapter. Some of the voltages found in amateur equipment can be fatal! Only 50 mA flowing through the body is painful; 100 to 500 mA is usually fatal. Under certain conditions, as little as 24 V can kill.

Make sure you are 100% familiar with all safety rules and the dangerous conditions that might exist in the equipment you

are servicing. Remember, if the equipment is not working properly, dangerous conditions may exist where you don't expect them. Treat every component as potentially "live."

Some older equipment uses "ac/dc" circuitry. In this circuit, one side of the chassis is connected directly to the ac line. This is an electric shock waiting to happen.

A list of safety rules can be found in **Table 27.1**. You should also read the **Safety** chapter of this *Handbook* before you proceed.

## GETTING HELP

Other hams may be able to help you with your troubleshooting and repair problems,

**Table 27.1**  
**Safety Rules**

1. Keep one hand in your pocket when working on live circuits or checking to see that capacitors are discharged.
2. Include a conveniently located ground-fault current interrupter (GFCI) circuit breaker in the workbench wiring.
3. Use grounded plugs and receptacles on all equipment that is not double insulated.
4. Use double insulated equipment or a GFCI circuit when working: outdoors, on a concrete or dirt floor, or near standing water.
5. Use an isolation transformer when working on ac/dc devices.
6. Switch off the power, ground the positive lead from the supply and discharge capacitors when making circuit changes.
7. Do not subject electrolytic capacitors to: excessive voltage, ac voltage or reverse voltage.
8. Test leads should be well insulated.
9. Do not work alone!
10. Wear safety glasses for protection against sparks and metal fragments.
11. Always use a safety belt when working above ground level.
12. Wear shoes with nonslip soles that will support your feet when climbing.
13. Wear rubber-sole shoes or use a rubber mat when standing on the ground or on a concrete floor.
14. Wear a hard hat when someone is working above you.
15. Be careful with tools that may cause short circuits.
16. Replace fuses only with those having proper ratings.

either with a manual or technical help. Check with your local club or repeater group. You may get lucky and find a troubleshooting “wizard.” (On the other hand, you may get some advice that is downright dangerous, so be selective.) You can also place a classified ad in one of the ham magazines, looking for a rare manual.

Your fellow hams in the ARRL Field organization may also help. Technical Coordinators (TCs) and Technical Specialists (TSs) are volunteers who are willing to help hams with technical questions. For the name and address of a local TC or TS, contact your Section Manager (listed on page 8 of any recent issue of *QST*).

## THEORY

To fix electronic equipment, you need to understand the system and circuits you are troubleshooting. A working knowledge of electronic theory, circuitry and components is an important part of the process. If necessary, review the electronic and circuit theory explained in the other chapters of this book. When you are troubleshooting, you are looking for the unexpected. Knowing how circuits are supposed to work will help you to look for things that are out of place.

## TEST EQUIPMENT

Many of the steps involved in troubleshooting efficiently require the use of test equipment. We cannot see electrons flow. However, electrons do affect various devices in our equipment, with results we can measure.

Some people think they need expensive test instruments to repair their own equipment. This is not so! In fact, you probably already own the most important instruments. Some others may be purchased inexpensively, rented, borrowed or built at home. The test equipment available to you may limit the kind of repairs you can do, but you will be surprised at the kinds of repair work you can do with simple test equipment.

### Senses

Although they are not “test equipment” in the classic sense, your own senses will tell you as much about the equipment you are trying to fix as the most-expensive spectrum analyzer. We each have some of these natural “test instruments.”

**Eyes** — Use them constantly. Look for evidence of heat and arcing, burned components, broken connections or wires, poor solder joints or other obvious visual problems.

**Ears** — Severe audio distortion can be detected by ear. The “snaps” and “pops”

of arcing or the sizzling of a burning component may help you track down circuit faults. An experienced troubleshooter can diagnose some circuit problems by the sound they make. For example, a bad audio-output IC sounds slightly different than a defective speaker.

**Nose** — Your nose can tell you a lot. With experience, the smells of ozone, an overheating transformer and a burned carbon-composition resistor each become unique and distinctive.

**Finger** — Carefully use your fingers to measure low heat levels in components. Small-signal transistors can be fairly warm to the touch; anything hotter can indicate a circuit problem. (Be careful; some high-power devices or resistors can get downright hot during normal operation.)

**Brain** — More troubleshooting problems have been solved with a VOM and a brain than with the most expensive spectrum analyzer. You must use your brain to analyze data collected by other instruments.

### “Internal” Equipment

Some “test equipment” is included in the equipment you repair. Nearly all receivers include a speaker. An S meter is usually connected ahead of the audio chain. If the S meter shows signals, it indicates that the RF and IF circuitry is probably functioning. Analyze what the unit is doing and see if it gives you a clue.

Some older receivers include a crystal frequency calibrator. The calibrator signal, which is rich in harmonics, is injected in the RF chain close to the antenna jack and may be used for signal tracing and alignment.

### Bench Equipment

Here is a summary of test instruments and their applications. Some items serve several purposes and may substitute for others on the list. The list does not cover all equipment available, only the most common and useful instruments. The theory and operation of much of this test equipment is discussed in more detail in the **Test** chapter.

**Multimeters** — The multimeter is the most often used piece of test equipment. This group includes vacuum-tube voltmeters (VTVMs), volt-ohm-milliammeters (VOMs), field-effect transistor VOMs (FETVOMs) and digital multimeters (DMMs). Multimeters are used to read bias voltages, circuit resistance and signal level (with an appropriate probe). They can test resistors, capacitors (within certain limitations), diodes and transistors.

DMMs have become quite inexpensive.

Their high input impedance, accuracy and flexibility are well worth the cost. Many of them contain other test equipment as well, such as capacitance meters, frequency counters, transistor testers and even digital thermometers. Some DMMs are affected by RF, so most technicians keep an analog-display VOM on hand for use near RF equipment.

When buying an analog meter, look for one with an input impedance of 20 k $\Omega$ /V or better. Reasonably priced models are available with 30 k $\Omega$ /V (\$35) and 50 k $\Omega$ /V (\$40). The 10 M $\Omega$  or better input impedance of DMMs, FETVOMs, VTVMs and other electronic voltmeters makes them the preferred instruments for voltage measurements.

**Test leads** — Keep an assortment of wires with insulated, soldered alligator clips. Commercially made leads have a high failure rate because they use small wire that is not soldered to the clips; it is best to make your own.

Open wire leads (Fig 27.1A) are good for dc measurements, but they can pick up unwanted RF energy. This problem is reduced somewhat if the leads are twisted together (Fig 27.1B). A coaxial cable lead is much better, but its inherent capacitance can affect RF measurements.

The most common probe is the low-capacitance ( $\times 10$ ) probe shown in Fig 27.1C. This probe isolates the oscilloscope from the circuit under test, preventing the ‘scope’s input and test-probe capacitance from affecting the circuit and changing the reading. A network in the probe serves as a 10:1 divider and compensates for frequency distortion in the cable and test instrument.

Demodulator probes (see the **Test** chapter and the schematic shown in Fig 27.1D) are used to demodulate or detect RF signals, converting modulated RF signals to audio that can be heard in a signal tracer or seen on a low-bandwidth ‘scope.

You can make a probe for inductive coupling as shown in Fig 27.1E. Connect a two- or three-turn loop across the center conductor and shield before sealing the end. The inductive pick up is useful for coupling to high-current points.

**RF power and SWR meters** — Every shack should have one. It is used to measure forward and reflected RF power. A standing-wave ratio (SWR) meter can be the first indicator of antenna trouble. It can also be used between an exciter and power amplifier to spot an impedance mismatch.

Simple meters indicate relative power SWR and are fine for Transmatch adjustment and line monitoring. However, if you want to make accurate measurements a

calibrated wattmeter with a directional coupler is required.

**Dummy load** — A dummy load is a necessity in any shack. Do not put a signal on the air while repairing equipment. Defective equipment can generate signals that interfere with other hams or other radio services. A dummy load also provides a known, matched load (usually  $50\ \Omega$ ) for use during adjustments.

When buying a dummy load, avoid used, oil-cooled dummy loads unless you can be sure that the oil does not contain PCBs. This biologically hazardous compound was common in transformer oil until a few years ago.

**Dip meter** — This device is often called a transistor dip meter or a grid-dip oscillator from vacuum-tube days.

Most dip meters can also serve as an

absorption frequency meter. In this mode, measurements are read at the current peak, rather than the dip. Some meters have a connection for headphones. The operator can usually hear signals that do not register on the meter. Because the dip meter is an oscillator, it can be used as a signal generator in certain cases where high accuracy or stability are not required.

When purchasing a dip meter, look for

Fig 27.1—An array of test probes for use with various test instruments.

one that is mechanically and electrically stable. The coils should be in good condition. A headphone connection is helpful. Battery operated models are easier to use for antenna measurements. Dip meters are not nearly as common as they once were.<sup>1</sup>

**Oscilloscope** — The oscilloscope, or 'scope, is the second most often used piece of test equipment, although a lot of repairs can be accomplished without one. The trace of a 'scope can give us a lot of information about a signal at a glance.

The simplest way to display a waveform is to connect the vertical amplifier of the 'scope to a point in the circuit through a simple test lead. When viewing RF, use a low-capacitance probe that has been adjusted to match the 'scope. Select the vertical gain and time-base (horizontal scale, Fig 27.2) for the most useful displayed waveform.

A 'scope waveform shows voltage (if

<sup>1</sup>The ARRL has prepared a list of dip-meter sources. Send an SASE to the Technical Information Service Secretary along with a specific request for the "Dip Meter" file.

Fig 27.2—An oscilloscope display showing the relationship between time-base setting and graticule lines.

Fig 27.3—Information available from a typical oscilloscope display of a waveform.

calibrated), approximate period (frequency is the reciprocal of the period) and a rough idea of signal purity (see Fig 27.3). If the 'scope has dual-trace capability (meaning it can display two signals at once), a second waveform may be displayed and compared to the first. When the two signals are taken from the input and output of a stage, stage linearity and phase shift can be checked (see Fig 27.4).

An important specification of an oscilloscope is its amplifier bandwidth. This tells us the frequency at which amplifier response has dropped 3 dB. The instrument will display higher frequencies, but its accuracy at higher frequencies is not known. Even well below its rated bandwidth a 'scope is not capable of much more

Fig 27.4—A dual-trace oscilloscope display of amplifier input and output waveforms.

than about 5% accuracy. This is adequate for most amateur applications.

An oscilloscope will show gross distortions of audio and RF waveforms, but it cannot be used to verify that a transmitter meets FCC regulations for harmonics and spurious emissions. Harmonics that are down only 20 dB from the fundamental would be illegal in most cases, but they would not change the oscilloscope waveform enough to be seen.

When buying a 'scope, get the greatest bandwidth you can afford. Old Hewlett-Packard or Tektronix 'scopes are usually quite good for amateur use.

**Signal generator** — Although signal generators have many uses, in troubleshooting they are most often used for signal injection (more about this later) and alignment.

An AF/RF signal-injector schematic is shown in Fig 27.5. If frequency accuracy is needed, the crystal-controlled signal source of Fig 27.6 can be used. The AF/RF circuit provides usable harmonics up to 30 MHz, while the crystal controlled oscillator will function with crystals from 1 to 15 MHz. These two projects are not meant to compete with standard signal generators, but they are adequate for signal injection.<sup>2</sup> A better generator is

<sup>2</sup>More information about the signal injector and signal sources appears in, "Some Basics of Equipment Servicing," February 1982 *QST* (Feedback, May 1982).

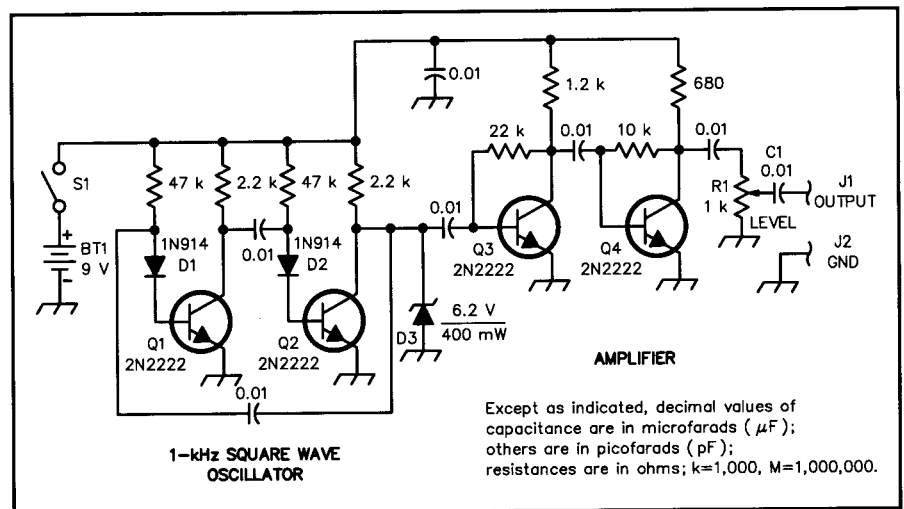

Fig 27.5—Schematic of the AF/RF signal injector. All resistors are  $\frac{1}{4}$ -W, 5% carbon units, and all capacitors are disc ceramic. A full-size etching pattern and parts-placement diagram are available from the ARRL Technical Department Secretary for an SASE. Ask for the "1995 Handbook Signal Injector" template.

BT1 — 9-V battery.  
D1, D2 — Silicon switching diode, 1N914 or equiv.  
D3 — 6.2-V, 400-mW Zener diode.  
J1, J2 — Banana jack.

Q1-Q4 — General-purpose silicon NPN transistors, 2N2222 or similar.  
R1 — 1-k $\Omega$  panel-mount control.  
S1 — SPST toggle switch.

required for receiver alignment or for receiver quality testing.

When buying a generator, look for one that can generate a sine wave signal. A good signal generator is double or triple shielded against leakage. Fixed-frequency audio should be available for modulation of the RF signal and for injection into audio stages. The most versatile generators can generate amplitude and frequency modulated signals.

Good generators have stable frequency controls with no backlash. They also have multiposition switches to control signal level. A switch marked in dBm is a good indication that you have located a high-quality test instrument. The output jack should be a coaxial connector (usually a BNC or N), not the kind used for microphone connections.

Some older, high-quality units are common. Look for World War II surplus units of the URM series, Boonton, GenRad, Hewlett-Packard, Tektronix, Measurements Inc or other well-known brand names. Some home-built signal generators may be quite good, but make sure to check construction techniques, level control and shielding quality.

**Signal tracer** — Signals can be traced with a voltmeter and an RF probe, a dip meter with headphones or an oscilloscope, but there are some devices made especially for signal tracing. A signal tracer is primarily a high-gain audio amplifier. It may have a built-in RF detector, or rely on an external RF probe. Most convert the traced signal to audio through a speaker.

The tracer must function as a receiver and detector for each frequency range in the test circuit. A high-impedance tracer input is necessary to prevent circuit loading.

A general-coverage receiver can be used to trace RF or IF signals, if the receiver covers the necessary frequency range. Most receivers, however, have a low-impedance input that severely loads the test circuit. To minimize loading, use a capacitive probe or loop pickup. When the probe is held near the circuit, signals will be picked up and carried to the receiver. It may also pick up stray RF, so make sure you are listening to the correct signal by switching the circuit under test on and off while listening.

**Tube tester** — Vacuum-tube testers used to be found in nearly every drug or department store. They are scarce now because tubes are no longer used in modern consumer or (most) amateur equipment. Older tube gear is found in many ham shacks or flea markets, though. There are many aficionados of vintage gear who enjoy working with old vacuum-tube equipment.

Most simple tube testers measure the cathode emission of a vacuum tube. Each grid is shorted to the plate through a switch and the current is observed while the tube operates as a diode. By opening the switches from each grid to the plate (one at a time), we can check for opens and shorts. If the plate current does not drop slightly as a switch is opened, the element connected to that switch is either open or shorted to another element. (We cannot tell an open from a short with this test.) The emission tester does not necessarily indicate the ability of a tube to amplify.

Other tube testers measure tube gain (transconductance). Some transconductance testers read plate current with a fixed bias network. Others use an ac signal to drive the tube while measuring plate current.

Most tube testers also check interelement leakage. Contamination inside the tube envelope may result in current leakage between elements. The paths can have high resistance, and may be caused by gas or deposits inside the tube. Tube testers use a moderate voltage to check for leakage. Leakage can also be checked with an ohmmeter using the  $\times 1\text{M}$  range, depending on the actual spacing of tube elements.

**Transistor tester** — Transistor testers are similar to transconductance tube testers. Device current is measured while the device is conducting or while an ac signal is applied at the control terminal. Commercial surplus units are often seen at ham flea markets. Some DMMs being sold

today also include a built-in, simple transistor tester.

Most transistor failures appear as either an open or shorted junction. Opens and shorts can be found easily with an ohmmeter; a special tester is not required.

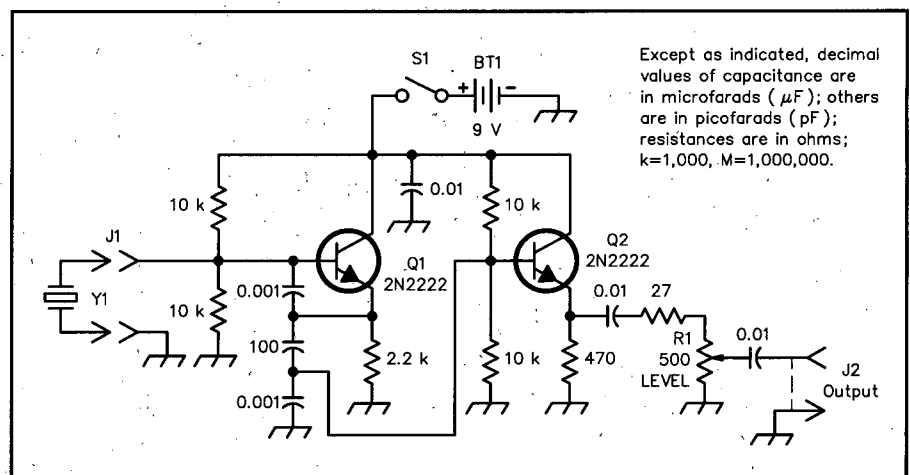

Transistor gain characteristics vary widely however, even between units with the same device number. Testers can be used to measure the gain of a transistor. A tester that uses dc signals measures only transistor dc alpha and beta. Testers that apply an ac signal show the ac alpha or beta. Better testers also test for leakage.

In addition to telling you whether a transistor is good or bad, a transistor tester can help you decide if a particular transistor has sufficient gain for use as a replacement. It may also help when matched transistors are required. The final test is the repair circuit.

**Frequency meter** — Most frequency counters are digital units, often able to show frequency to a 1-Hz resolution. Some older "analog" counters are sometimes found surplus, but a low-cost digital counter will out-perform even the best of these old "classics."

**Power supplies** — A well-equipped test bench should include a means of varying the ac-line voltage, a variable-voltage regulated dc supply and an isolation transformer.

AC-line voltage varies slightly with load. An autotransformer with a movable tap lets you boost or reduce the line volt-

**Fig 27.6 — Schematic of the crystal-controlled signal source. All resistors are  $\frac{1}{4}$ -W, 5% carbon units, and all capacitors are disc ceramic. A full-size etching pattern and parts-placement diagram are available from the ARRL Technical Department Secretary for an SASE. Ask for the "1995 Handbook Crystal Controlled Signal Source" template.**

**BT1** — 9-V transistor radio battery.

**J1** — Crystal socket to match the crystal type used.

**J2** — RCA phono jack or equivalent.

**Q1, Q2** — General-purpose silicon NPN transistors, 2N2222 or similar.

**R1** — 500- $\Omega$  panel-mount control.

**S1** — SPST toggle switch.

**Y1** — 1 to 15-MHz crystal.

age slightly. This is helpful to test circuit functions with supply-voltage variations.

As mentioned earlier, ac/dc radios must be isolated from the ac line during testing and repair. Keep an isolation transformer handy if you want to work on table-model broadcast radios or television sets (check for other ac/dc equipment, too. Even some old phonographs or Amateur Radio transceivers used this dangerous circuit design).

A good multivoltage supply will help with nearly any analog or digital troubleshooting project. Several of the distributors listed in the **References** chapter stock bench power supplies. A variable-voltage dc supply may be used to power various small items under repair or provide a variable bias supply for testing active devices. Construction details for a laboratory power supply appear in the **Power Supplies** chapter.

If you want to work on vacuum-tube gear, the maximum voltage available from the dc supply should be high enough to serve as a plate or a bias supply for common tubes (about 300 to 400 V ought to do it).

**Accessories** — There are a few small items that may be used in troubleshooting. You may want to keep them handy.

Many circuit problems are sensitive to temperature. A piece of equipment may work well when first turned on (cold) but

fail as it warms up. In this case, a cold source will help you find the intermittent connection. When you cool the bad component, the circuit will suddenly start working again (or stop working). Cooling sprays are available from most parts suppliers.

A heat source helps locate components that fail only when hot. A small incandescent lamp can be mounted in a large piece of sleeve insulation to produce localized heat for test purposes.

A heat source is usually used in conjunction with a cold source. If you have a circuit that stops working when it warms up, heat the circuit until it fails, then cool the components one by one. When the circuit starts working again, the last component sprayed was the bad one.

A stethoscope (with the pickup removed — see Fig 27.7) or a long piece of sleeve insulation can be used to listen for arcing or sizzling in a circuit.

## WHERE TO BEGIN

### New Construction

In most repair work, the technician is aided by the knowledge that the circuit once worked. It is only necessary to find the faulty part(s) and replace it. This is not so with newly constructed equipment. Repair of equipment with no working history is a special, and difficult, case. You may be dealing with a defective component, construction error or even a faulty design. Carefully checking for these defects can save you hours.

### All Equipment

#### Check the Obvious

Try the easy things first. If you are able to solve the problem by replacing a fuse or reconnecting a loose cable, you might be able to avoid a lot of effort. Many experienced technicians have spent hours troubleshooting a piece of equipment only to learn the hard way that the on/off switch was “off” or that they were not using the equipment properly.

Read the manual! Your equipment may be working as designed. Many electronic “problems” are caused by a switch that is set in the wrong position, or a unit that is being asked to do something it was not designed to do. Before you open up your equipment for major surgery, make sure you are using it correctly.

Next, make sure the equipment is plugged in, that the ac outlet does indeed have power, that the equipment is switched “on” and that all of the fuses are good. If the equipment uses batteries or an external power supply, make sure these are working.

Check that all wires, cables and accessories are working and plugged in to the right connectors or jacks. In a “system,” it is often difficult to be sure which component or subsystem is bad. Your transmitter may not work on SSB because the transmitter is bad, but it could also be a bad microphone.

Connector faults are more common than component troubles. Consider poor connections as prime suspects in your troubleshooting detective work. Do a thorough inspection of the connections. Is the antenna connected? How about the speaker, fuses and TR switch? Are transistors and ICs firmly seated in their sockets? Are all interconnection cables sound and securely connected? Many of these problems are obvious to the eye, so look around carefully.

### Simplify the Problem

If the broken equipment is part of a system, you need to find out exactly which part of the system is bad. For example, if your amateur station is not putting out any RF, you need to determine if it is a microphone problem, a transmitter problem, an amplifier problem or a problem somewhere in your station wiring. If you are trying to diagnose a bad channel on your home modular stereo system, it could be anything from a bad cable to a bad amplifier to a bad speaker.

Simplify the system as much as possible. To troubleshoot the “no-RF” problem, temporarily eliminate the amplifier from the station configuration. To diagnose the stereo system, start troubleshooting by checking just the amplifier with a set of known good headphones. Simplifying the problem will often isolate the bad component quickly.

### Documentation

Once you have determined that a piece of equipment is indeed broken, you need to do some preparation before you diagnose and fix it. First, locate a schematic diagram and service manual. It is possible to troubleshoot without a service manual, but a schematic is almost indispensable.

The original equipment manufacturer is the best source of a manual or schematic. However, many old manufacturers have gone out of business. Several sources of equipment manuals are listed in the **References** chapter.

If all else fails, you can sometimes reverse engineer a simple circuit by tracing wiring paths and identifying components to draw your own schematic. If you have access to the databooks for the active devices used in the circuit, the pin-out diagrams and applications notes will

Fig 27.7 — A stethoscope, with the pickup removed, is used to listen for arcing in crowded circuits.

sometimes be enough to help you understand and troubleshoot the circuit.

### Define Problems

To begin troubleshooting, define the problem accurately. Ask yourself these questions:

1. What functions of the equipment do not work as they should; what does not work at all?
2. What kind of performance can you realistically expect?
3. Has the trouble occurred in the past? (Keep a record of troubles and maintenance in the owner's manual or log book.)

Write the answers to the questions. The information will help with your work, and may help service personnel if their advice or professional service is required.

### Take It Apart

All of the preparation work has been done. It is time to really dig in. You usually will have to start by taking the equipment apart. This is the part that can trap the unwary technician. Most experienced service technicians can tell you the tale of the equipment they took apart and were unable to easily put back together. Don't let it happen to you.

Take lots of notes about the way you take it apart. Take notes about each component you remove. Write down the order in which you do things, color codes, part placements, cable routings, hardware notes and anything else you think you might need to be able to reassemble the equipment weeks from now when the back-ordered part comes in.

Put all of the screws in one place. A plastic jar with a lid works well; if you drop it the plastic is not apt to break and the lid will keep all the parts from flying around the work area (you will never find them all). It may pay to have a separate labeled container for each subsystem.

### Look Around

Many service problems are visible, if you look for them carefully. Many a technician has spent hours tracking down a failure, only to find a bad solder joint or burned component that would have been spotted in careful inspection of the printed-circuit board. Start troubleshooting by carefully inspecting the equipment.

It is time consuming, but you really need to look at every connector, every wire, every solder joint and every component. A connector may have loosened, resulting in an open circuit. You may spot broken wires or see a bad solder joint. Flexing the printed-circuit board or tugging on com-

ponents a bit while looking at their solder joints will often locate a defective solder job. Look for scorched components.

Make sure all of the screws securing the printed-circuit board are tight and making good electrical contact. (Do not tighten the adjusting screws, however! You will ruin the alignment.) See if you can find evidence of previous repair jobs; these may

not have been done properly. Make sure that each IC is firmly seated in its socket. Look for pins folded underneath the IC rather than making contact with the socket. If you are troubleshooting a newly constructed circuit, make sure each part is of the correct value or type number and is installed correctly.

If your careful inspection doesn't reveal

### Look for the Obvious

The best example of how looking for the obvious can save a lot of repair time comes from my days as the manager of an electronics service shop. We had hired a young engineering graduate to work for us part time. He was the proud holder of a First-Class FCC Radiotelephone license (the predecessor to today's General Radiotelephone license). He was a likable sort, but, well . . . the chip on his young shoulder was a bit hard to take sometimes.

One day, I had asked him to repair a "tube-type" FM tuner. He had been poking around without success: hooking up a voltmeter, oscilloscope and signal generator, pretty much in that order. Finally, in total exasperation, he pronounced that the unit was beyond economical repair and suggested that I return it to the customer unfixed. The particular customer was a "regular," so I wanted to be sure of the diagnosis before I sent the tuner back. I told the tech I wanted to take a look at it before we wrote it off.

He started to expound loudly that there was no way that I, a lowly technician (even though I was also his boss) could find a problem that he, an engineering graduate and holder of a First Class . . . you get the idea. I did remind him gently that I was the boss, and he, realizing that I had him there, stepped aside, mumbling something about my suiting myself. He stepped back to gloat when I couldn't find it either.

I began by giving the tuner a thorough visual inspection. I looked it over carefully from stern to stern, while listening to our young apprentice proclaiming with certainty that one cannot fix electronic equipment by merely looking at it. I didn't see anything obviously wrong, so I decided to move wires and components around, looking for a bad solder joint or broken component. Of course, I had to listen to him telling me that one cannot possibly find bad components by touch. Unfortunately for our loud friend, he couldn't have been more wrong.

I grabbed hold of a ceramic bypass capacitor to give it a little wiggle, and much to my surprise it was hot enough to cause some real pain. I kept my composure; it was an opportunity for a good learning experience. Ceramic capacitors don't get very hot unless they are either shorted or very leaky. I kept silent and never let on that my finger "probe" had indeed located the bad part. I set the tuner down, sighed a bit, and then looked him right in the eye when I pointed to the capacitor and said "Change that part!"

They probably heard his bellowing in the next county! He went on and on about how there was just no way in the world that I could tell a good part from a bad part by just looking and touching things. He alternated between accusing me of pulling his leg and guessing, then back to just plain bellowing again. After letting this "source of great noise" run his course, I offered the ultimate shop challenge — I bet him a can of soda pop.

The traditional shop challenge did the trick. He smugly grabbed a replacement part from the bin and got out his soldering iron. In a matter of seconds (a new shop record, I believe) the capacitor was installed. He hooked the tuner up to a test amplifier and turned them on. After a couple of seconds, he smugly turned to me and started an "I told ya' so!" Just then, the last tube warmed up and the sounds of our local rock station blasted out of the speaker. He stopped in mid "toldya" and stared at the tuner in disbelief. The tempo and pitch of his voice jumped by an order of magnitude as he asked me how I managed to fix the tuner without using even an ohmmeter to test a fuse. It was weeks before I told him — the soda pop tasted especially good.

The moral of the story is clear; sophisticated test equipment and procedures are useful in troubleshooting, but they are no substitute for the experience of a veteran troubleshooter. — Ed Hare, KA1CV, ARRL Laboratory Supervisor

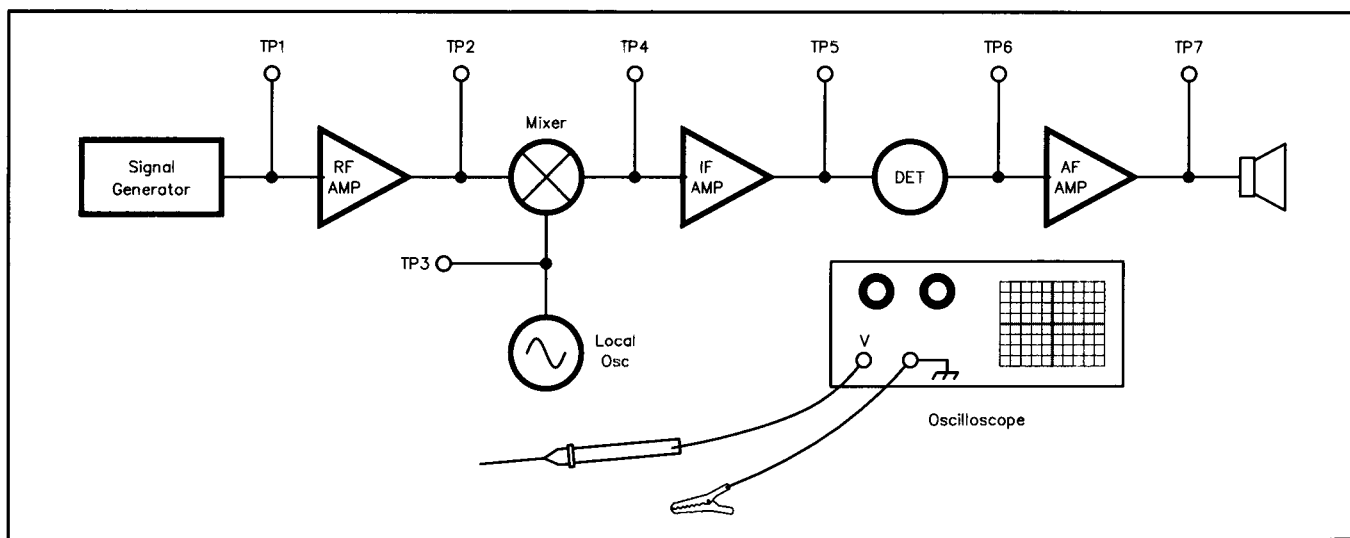

Fig 27.8 — Signal tracing in a simple receiver.

Fig 27.9 — The effect of circuit impedance on an oscilloscope display. Although the circuit functions as a current amplifier, the change in impedance from TP1 to TP2 results in the traces described. This is a common-collector amplifier.

anything, it is time to apply power to the unit under test and continue the process. Observe all safety precautions while troubleshooting equipment. There are voltages inside some equipment that can kill you. If you are not qualified to work safely with the voltages and conditions inside of the equipment, do not proceed. See Table 27.1 and the **Safety** chapter.

#### Other Senses

With power applied to the unit, listen for arcs and look and smell for smoke. If no problems are apparent, you will have to start testing the various parts of the circuit.

### VARIOUS APPROACHES

There are two fundamental approaches to troubleshooting: the systematic approach and the instinctive approach. The systematic approach uses a defined process to analyze and isolate the problem. An instinctive approach relies on troubleshooting experience to guide you in selecting which circuits to test and which tests to perform. The systematic approach is usually chosen by beginning troubleshooters.

#### At the Block Level

The block diagram is a road map. It shows the signal paths for each circuit function. These paths may run together, cross occasionally or not at all. Those blocks that are not in the paths of faulty functions can be eliminated as suspects. Sometimes the symptoms point to a single block, and no further search is necessary.

In cases where more than one block is suspect, several approaches may be used. Each requires testing a block or stage. Signal injection, signal tracing, instinct or combination of all techniques may be used to diagnose and test electronic equipment.

#### Systematic Approaches

The instinctive approach works well for those with years of troubleshooting experience. Those of us who are new to this game need some guidance. A systematic approach is a disciplined procedure that allows us to tackle problems in unfamiliar equipment with a reasonable hope of success.

There are two common systematic approaches to troubleshooting at the block level. The first is signal tracing; the second is signal injection. The two techniques

are very similar. Differences in test equipment and the circuit under test determine which method is best in a given situation. They can often be combined.

#### Power Supplies

You may be able to save quite a bit of time if you test the power supply first. All of the other circuits may be dead if the power supply is not working. Power supply diagnosis is discussed in detail later in this chapter.

#### Signal Tracing

In signal tracing, start at the beginning of a circuit or system and follow the signal through to the end. When you find the signal at the input to a specific stage, but not at the output, you have located the defective stage. You can then measure voltages and perform other tests on that stage to locate the specific failure. This is much faster than testing every component in the unit to determine which is bad.

It is sometimes possible to use over-the-air signals in signal tracing, in a receiver for example. However, if a good signal generator is available, it is best to use it as the signal source. A modulated signal source is best.

Signal tracing is suitable for most types of troubleshooting of receivers and analog amplifiers. Signal tracing is the best way to check transmitters because all of the necessary signals are present in the transmitter by design. Most signal generators cannot supply the wide range of signal levels required to test a transmitter.

#### Equipment

A voltmeter, with an RF probe, is the

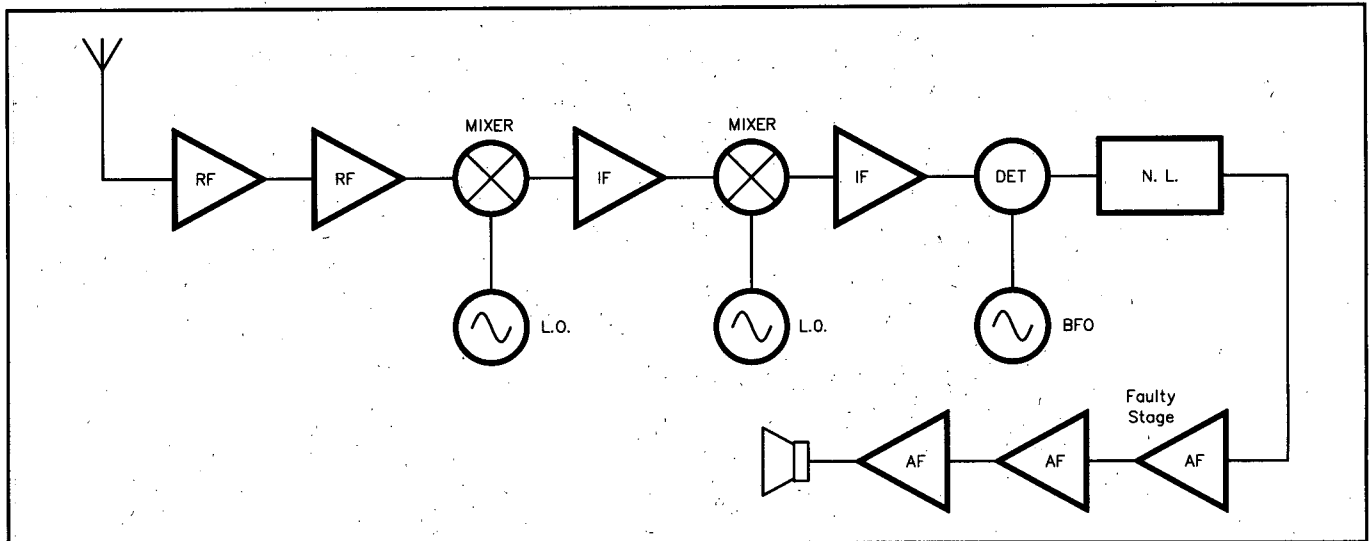

Fig 27.10 — The 14-stage receiver diagnosed by the “divide and conquer” technique.

most common instrument used for signal tracing. Low-level signals cannot be measured accurately with this instrument. Signals that do not exceed the junction drop of the diode in the probe will not register at all, but the presence, or absence, of larger signals can be observed.

A dedicated signal tracer can also be used. It is essentially an audio amplifier. An experienced technician can usually judge the level and distortion of the signal by ear. You cannot use a dedicated signal tracer to follow a signal that is not amplitude modulated (single sideband is a form of AM). Signal tracing is not suitable for tracing CW signals, FM signals or oscillators. To trace these, you will have to use a voltmeter and RF probe or an oscilloscope.

An oscilloscope is the most versatile signal tracer. It offers high input impedance, variable sensitivity, and a constant display of the traced waveform. If the oscilloscope has sufficient bandwidth, RF signals can be observed directly. Alternatively, a demodulator probe can be used to show demodulated RF signals on a low-bandwidth 'scope. Dual-trace scopes can simultaneously display the waveforms, including their phase relationship, present at the input and output of a circuit.

#### Procedure

First, make sure that the circuit under test and test instruments are isolated from the ac line by transformers. Set the signal source to an appropriate level and frequency for the unit you are testing. For a receiver, a signal of about 100  $\mu\text{V}$  should be plenty. For other circuits, use the schematic, an analysis of circuit function and your own good judgment to set the signal level.

In signal tracing, start at the beginning

and work toward the end of the signal path. Switch on power to the test circuit and connect the signal-source output to the test-circuit input. Place the tracer probe at the circuit input and ensure that you can hear the test signal. Observe the characteristics of the signal if you are using a 'scope (see Fig 27.8). Compare the detected signal to the source signal during tracing.

Move the tracer probe to the output of the next stage and observe the signal. Signal level should increase in amplifier stages and may decrease slightly in other stages. The signal will not be present at the output of a “dead” stage.

Low-impedance test points may not provide sufficient signal to drive a high-impedance signal tracer, so tracer sensitivity is important. Also, in some circuits the output level appears low where there is an impedance change from input to output of a stage (see Fig 27.9). For example, the circuit in Fig 27.9 is a common-collector current amplifier with a high input impedance and low output impedance. The voltages at TP1 and TP2 are approximately equal and in phase.

There are two signals — the test signal and the local oscillator signal — present in a mixer stage. Loss of either one will result in no output from the mixer stage. Switch the signal source on and off repeatedly to make sure that the tracer reading varies (it need not disappear) with source switching.

#### Signal Injection

Like signal tracing, signal injection is particularly suited to some situations. Signal injection is a good choice for receiver troubleshooting because the receiver already has a detector as part of the design.

It is suitable for either high- or low-impedance circuits and can be used with vacuum tubes, transistors or ICs.

#### Equipment

If you are testing equipment that does not include a suitable detector as part of the circuit, some form of signal detector is required. Any of the instruments used for signal tracing are adequate.

Most of the time, your signal injector will be a signal generator. There are other injectors available, some of which are square-wave audio oscillators rich in RF harmonics (see Fig 27.5). These are usually built into a pen-sized case with a test probe at the end. These “pocket” injectors do have their limits because you can't vary their output level or determine their frequency. They are still useful, though, because most circuit failures are caused by a stage that is completely dead.

Consider the signal level at the test point when choosing an instrument. The signal source used for injection must be able to supply appropriate frequencies and levels for each stage to be tested. For example, a typical superheterodyne receiver requires AF, IF and RF signals that vary from 6 V at AF, to 0.2  $\mu\text{V}$  at RF. Each conversion stage used in a receiver requires another IF from the signal source.

#### Procedure

If an external detector is required, set it to the proper level and connect it to the test circuit. Set the signal source for AF and inject a signal directly into the signal detector to test operation of the injector and detector. Move the signal source to the input of the preceding stage and observe the signal. Continue moving the signal source to the inputs of successive stages.

When you inject the signal source to the input of the defective stage, there will be no output. Prevent stage overload by reducing the level of the injected signal as testing progresses through the circuit. Use suitable frequencies for each tested stage.

Make a rough check of stage gain by injecting a signal at the input and output of an amplifier stage. You can then compare how much louder the signal is when injected at the input. This test may mislead you if there is a radical difference in impedance from stage input to output. Understand the circuit operation before testing.

Mixer stages present a special problem because they have two inputs, rather than one. A lack of output signal from a mixer can be caused by either a faulty mixer or a faulty local oscillator (LO). Check oscillator operation with a scope or absorption wavemeter, or by listening on another receiver. If none of these instruments are available, inject the frequency of the LO at the LO output. If a dead oscillator is the only problem, this should restore operation.

If the oscillator is operating, but off frequency, a multitude of spurious responses will appear. A simple signal injector that produces many frequencies simultaneously is not suitable for this test. Use a well-shielded signal generator set to an appropriate level at the LO frequency.

### Divide and Conquer

Under certain conditions, the block search may be speeded by testing at the middle of successively smaller circuit sections. Each test limits the fault to one half of the remaining circuit (see **Fig 27.10**). Let's say the receiver has 14 stages and the fault is in stage 12. This approach requires only four tests to locate the faulty stage, a substantial saving of time.

This "divide and conquer" tactic cannot be used in equipment that splits the signal path between the input and the output. Test readings taken inside feedback loops are misleading unless you understand the circuit and the waveform to be expected at each point in the test circuit. It is best to consider all stages within a feedback loop as a single block during the block search.

Both signal tracing and signal injection procedures may be speeded by taking some diagnostic short cuts. Rather than check each stage sequentially, check a point halfway through the system. As an example:

An HF receiver is not working. There is absolutely no response from the speaker. First, substitute a suitable speaker — still no sound. Next, check the power supply — no problem there. No clues indicate any

particular stage. Signal tracing or injection must provide the answer.

Get out the signal generator and switch it on. Set the generator for a low-level RF signal, switch the signal off and connect the output to the receiver. Switch the signal on again and place a high-impedance signal-tracer probe at the antenna connection. Instantly, the tracer emits a strong audio note. Good; the test equipment is functioning.

Move the probe to the input of the receiver detector. As the tracer probe touches the circuit the familiar note sounds. Next, set the tracer for audio and place the probe halfway through the audio chain. It is silent! Move the probe halfway back to the detector, and the note appears once again. Yet, no signal is present at the output of the stage. You now know that the defect is somewhere between the two points tested. In this case, the third audio stage is faulty.

### The Instinctive Approach

In an "instinctive" approach to troubleshooting, you rely on your judgment and experience to decide where to start testing, what and how to test. When you immediately check power supply voltages, or the ac fuse on a unit that is completely nonfunctional, that is an example of an instinctive approach. If you are faced with a receiver that has distorted audio and immediately start testing the speaker and audio output stage, or if you immediately start checking the filter and bypass capacitors in an audio stage that is oscillating or "motorboating" you are troubleshooting on instinct.

Most of our discussion on the instinctive approach is really a collection of tips and guidelines. Read them to build your troubleshooting skills.

The check for connector problems mentioned at the beginning of this section is a good idea. Experience has shown connector faults to be so common that they should be checked even before a systematic approach begins.

When instinct is based on experience, searching by instinct may be the fastest procedure. If your instinct is correct, repair time and effort may be reduced substantially. As experience and confidence grow, the merits of the instinctive approach grow with them. However, inexperienced technicians who choose this approach are at the mercy of chance.

### TESTING WITHIN A STAGE

Once you have followed all of the troubleshooting procedures and have isolated your problem to a single defective stage or circuit, a few simple measure-

ments and tests will usually pinpoint one or more specific components that need adjustment or replacement.

First, check the parts in the circuit against the schematic diagram to be sure that they are reasonably close to the design values, especially in a newly built circuit. Even in a commercial piece of equipment, someone may have incorrectly changed them during attempted repairs. A wrong-value part is quite likely in new construction, such as a home-brew project.

### Voltage Levels

Check the circuit voltages. If the voltage levels are printed on the schematic, this is easy. If not, analyze the circuit and make some calculations to see what the circuit voltages should be. Remember, however, that the printed or calculated voltages are nominal; measured voltages may vary from the calculations.

When making measurements, remember the following points:

- Make measurements at device leads, not at circuit-board traces or socket lugs.
- Use small test probes to prevent accidental shorts.
- Never connect or disconnect power to solid-state circuits with the switch on.
- Consider the effect of the meter on measured voltages. A 20-k $\Omega$ /V meter may load down a high-impedance circuit and change the voltage.

Voltages may give you a clue to what is wrong with the circuit. If not, check the active device. If you can check the active device in the circuit, do so. If not, remove it and test it, or substitute a known good device. After connections, most circuit failures are caused directly or indirectly by a bad active device. The experienced troubleshooter usually tests or substitutes these first.

Analyze the other components and determine the best way to test each. There is additional information about electronic components in the electronic-theory chapters and in the **Component Data** chapter.

There are two voltage levels in most circuits (V+ and ground, for example). Most component failures (opens and shorts) will shift dc voltages near one of these levels.

Typical failures that show up as incorrect dc voltages include: open coupling transformers; shorted capacitors; open, shorted or overheated resistors and open or shorted semiconductors.

### Noise

A slight hiss is normal in all electronic circuits. This noise is produced whenever current flows through a conductor that is

warmer than absolute zero. Noise is compounded and amplified by succeeding stages. Repair is necessary only when noise threatens to obscure normally clear signals.

Semiconductors can produce hiss in two ways. The first is normal — an even white noise that is much quieter than the desired signal. Faulty devices frequently produce excessive noise. The noise from a faulty device is usually erratic, with pops and crashes that are sometimes louder than the desired signal. In an analog circuit, the end result of noise is usually sound. In a control or digital circuit, noise causes erratic operation: unexpected switching and so on.

Noise problems usually increase with temperature, so localized heat may help you find the source. Noise from any component may be sensitive to mechanical vibration. Tapping various components with an insulated screwdriver may quickly isolate a bad part. Noise can also be traced with an oscilloscope or signal tracer.

Nearly any component or connection can be a source of noise. Defective components are the most common cause of crackling noises. Defective connections are a common cause of loud, popping noises.

Check connections at cables, sockets and switches. Look for dirty variable-capacitor wipers and potentiometers. Mica trimmer capacitors often sound like lightning when arcing occurs. Test them by installing a series 0.01- $\mu$ F capacitor. If the noise disappears, replace the trimmer.

Potentiometers are particularly prone to noise problems when used in dc circuits. Clean them with spray cleaner and rotate the shaft several times.

Rotary switches may be tested by jumpering the contacts with a clip lead. Loose contacts may sometimes be repaired, either by cleaning, carefully rebending the switch contacts or gluing loose switch parts to the switch deck. Operate variable components through their range while observing the noise level at the circuit output.

### Oscillations

Oscillations occur whenever there is sufficient positive feedback in a circuit that has gain. (This can even include digital devices.) Oscillation may occur at any frequency from a low-frequency audio buzz (often called "motorboating") well up into the RF region.

Unwanted oscillations are usually the result of changes in the active device (increased junction or interelectrode capacitance), failure of an oscillation suppressing component (open decoupling or

bypass capacitors or neutralizing components) or new feedback paths (improper lead dress or dirt on the chassis or components). It can also be caused by improper design, especially in home-brew circuits. A shift in bias or drive levels may aggravate oscillation problems.

Oscillations that occur in audio stages do not change as the radio is tuned because the operating frequency, and therefore the component impedances, do not change. However, RF and IF oscillations usually vary in amplitude as operating frequency is changed.

Oscillation stops when the positive feedback is removed. Locating and replacing the defective (or missing) bypass capacitor may effect an improvement. The defective oscillating stage can be found more reliably with a signal tracer or oscilloscope.

### Amplitude Distortion

Amplitude distortion is the product of nonlinear operation. The resultant waveform contains not only the input signal, but new signals at other frequencies as well. All of the frequencies combine to produce the distorted waveform. Distortion in a transmitter gives rise to splatter, harmonics and interference.

Fig 27.11 shows some typical cases of distortion. Clipping (also called flattopping) is the consequence of excessive drive. The corners on the waveform show that harmonics are present. (A square wave contains the fundamental and all odd harmonics.) These odd harmonics would be heard well away from the operating frequency, possibly outside of amateur bands. Key clicks are similar to clipping.

Harmonic distortion produces radiation at frequencies far removed from the fundamental; it is a major cause of electromagnetic interference (EMI). Harmonics are generated in nearly every amplifier. When they occur in a transmitter, they are usually caused by insufficient transmitter filtering (either by design, or because of filter component failure).

Incorrect bias brings about unequal amplification of the positive and negative wave sections. The resultant waveform is rich in harmonics.

### Frequency Distortion

If a "broadband" amplifier, such as an audio amplifier, doesn't amplify all frequencies equally, there is frequency distortion. In many cases, this "frequency distortion" is deliberate, as in a transmitter microphone amplifier that has been designed to pass only frequencies from 200 to 2000 Hz. In most cases, the amateur's ability to detect and measure

(A)

(B)

(C)

**Fig 27.11 — Examples of distorted waveforms. The result of clipping is shown in A. Nonlinear amplification is shown in B. A pure sine wave is shown in C for comparison.**

distortion is limited by available test equipment.

### Distortion Measurement

A distortion meter is used to measure distortion of AF signals. A spectrum analyzer is the best piece of test gear to measure distortion of RF signals. If a distortion meter is not available, an estimation of AF distortion can sometimes be made with a function generator (sine and square waves) and an oscilloscope.

To estimate the amount of frequency distortion in an audio amplifier, set the generator for a square wave and look at it on the 'scope. (Use a low-capacitance probe.) The wave should show square corners and a flat top. Next, inject a square wave at the amplifier input and again look at the input wave on the 'scope. Any new distortion is a result of the test circuit loading the generator output. (If the wave shape is severely distorted, the test is not

valid.) Now, move the test probe to the test circuit output and look at the waveform. Refer to **Fig 27.12** to evaluate square-wave distortion and its cause.

The above applies only to audio amplifiers without frequency tailoring. In RF gear, the transmitter may have a very narrow audio passband, so inserting a square wave into the microphone input may result in an output that is difficult to interpret. The frequency of the square wave will have a significant effect.

Anything that changes the proper bias of an amplifier can cause distortion. This includes failures in the bias components, leaky transistors or vacuum tubes with interelectrode shorts. These conditions may mimic AGC trouble. Improper bias often results from an overheated or open resistor. Heat can cause resistor values to permanently increase. Leaky, or shorted capacitors and RF feedback can also produce distortion by disturbing bias levels. Distortion is also caused by circuit imbalance in Class AB or B amplifiers.

Oscillations in an IF amplifier may produce distortion. They cause constant, full AGC action, or generate spurious signals that mix with the desired signal. IF oscillations are usually evident on the S meter, which will show a strong signal even with the antenna disconnected.

### Alignment

Alignment is rarely the cause of an electronics problem. As an example, suppose an AM receiver suddenly begins producing weak and distorted audio. An inexperienced person frequently suspects poor alignment as a common problem. Even though the manufacturer's instructions and the proper equipment are not available, our "friend" (this would never be one of US!) begins "adjusting" the transformer

cores. Before long, the set is hopelessly misaligned. Now our misguided ham must send the radio to a shop for an alignment that was not needed before repairs were attempted.

Alignment does not shift suddenly. A normal signal tracing procedure would have shown that the signal was good up to the audio-output IC, but badly distorted after that. The defective IC that caused the problem would have been easily found and quickly replaced.

### Contamination

Contamination is another common service problem. Cold soda pop spilled into a hot piece of electronics is an extreme example (but one that does actually happen).

Conductive contaminants range from water to metal filings. Most can be removed by a thorough cleaning. Any of the residue-free cleaners can be used, but remember that the cleaner may also be conductive. Do not apply power to the circuit until the area is completely dry.

Keep cleaners away from variable-capacitor plates, transformers and parts that may be harmed by the chemical. The most common conductive contaminant is solder, either from a printed-circuit board "solder bridge" or a loose piece of solder deciding to surface at the most inconvenient time.

### Solder "Bridges"

In a typical PC-board solder bridge, the solder that is used to solder one component has formed a short circuit to another PC-board trace or component. Unfortunately, they are common in both new construction and repair work. Look carefully for them after you have completed any soldering, especially on a PC-board. It is even possible that a solder bridge may

exist in equipment you have owned for a long time, unnoticed until it suddenly decided to become a short circuit.

Related items are loose solder blobs, loose hardware or small pieces of component leads that can show up in the most awkward and troublesome places.

### Arcing

Arcing is a serious sign of trouble. It may also be a real fire hazard. Arc sites are usually easy to find because an arc that generates visible light or noticeable sound also pits and discolors conductors.

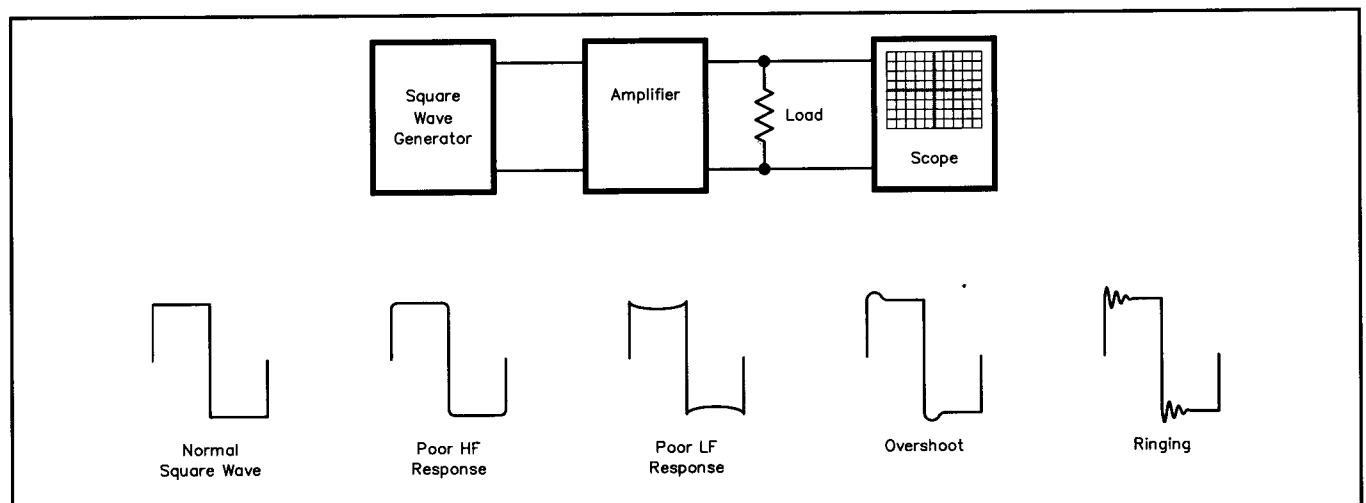

Arcing is caused by component failure, dampness, dirt or lead dress. If the dampness is temporary, dry the area thoroughly and resume operation. Dirt may be cleaned from the chassis with a residue-free cleaner. Arrange leads so high-voltage conductors are isolated. Keep them away from sharp corners and screw points.

Arcing occurs in capacitors when the working voltage is exceeded. Air-dielectric variable capacitors can sustain occasional arcs without damage, but arcing indicates operation beyond circuit limits. Transmatches working beyond their ability may suffer from arcing. A failure or high SWR in an antenna circuit may also cause transmitter arcing.

### Replacing Parts

If you have located a defective component within a stage, you need to replace it. When replacing socket mounted components, be sure to align the replacement part correctly. Make sure that the pins of the device are properly inserted into the socket.

Some special tools can make it easier to remove soldered parts. A chisel-shaped soldering tip helps pry leads from printed-circuit boards or terminals. A desoldering

**Fig 27.12 — Square-wave distortion and probable causes.**

iron or bulb forms a suction to remove excess solder, making it easier to remove the component. Spring-loaded desoldering pumps are more convenient than bulbs. Desoldering wick draws solder away from a joint when pressed against the joint with a hot soldering iron.

In all cases, remember that soldering tools and melted solder can be hot and dangerous! Wear protective goggles and clothing when soldering. A full course in first aid is beyond the scope of this chapter, but if you burn your fingers, run the burn immediately under cold water and seek first aid or medical attention. Always seek medical attention if you burn your eyes; even a small burn can develop into serious trouble.

## TYPICAL SYMPTOMS AND FAULTS

### Power Supplies

Many equipment failures are caused by power-supply trouble. Fortunately, most power-supply problems are easy to find and repair (see Fig 27.13). First, use a voltmeter to measure output. Loss of output voltage is usually caused by an open circuit. (A short circuit draws excessive current that opens the fuse, thus becoming an open circuit.)

Most fuse failures are caused by a shorted diode in the power supply or a shorted power device (RF or AF) in the failed equipment. More rarely, one of the filter capacitors can short. If the fuse has opened, turn off the power, replace the fuse and measure the load-circuit dc resistance. The measured resistance should be consistent with the power-supply ratings. A short or open load circuit indicates a problem.

If the measured resistance is too low, check the load circuit with an ohmmeter to locate the trouble. (Nominal circuit resistances are included in some equipment manuals.) If the load circuit resistance is normal, suspect a defective regulator IC or problem in the rest of the unit. Electrolytic capacitors fail with long (two years) disuse; the electrolytic layer may be reformed as explained later in this chapter.

IC regulators can oscillate, sometimes causing failure. The small-value capacitors on the input, output or adjustment pins of the regulator prevent oscillations. Check or replace these capacitors whenever a regulator has failed.

AC ripple (hum) is usually caused by low-value filter capacitors in the power supply. Less likely, hum can also be caused by excessive load, a regulation problem or RF feedback in the power supply. Look for a defective filter capacitor (usually open or low-value), defective regulator or shorted filter choke. In older equipment, the defective filter capacitor will often have visible leaking electrolyte. Look for corrosion residue at the capacitor leads. In new construction projects make sure RF energy is not getting into the power supply.

Here's an easy filter-capacitor test: Temporarily connect a replacement capacitor (about the same value and working voltage) across the suspect capacitor. If the hum goes away, replace the bad component permanently.

Once the faulty component is found, inspect the surrounding circuit and consider what may have caused the problem. Sometimes one bad component can cause another to fail. For example, a shorted filter capacitor increases current flow and burns out a rectifier diode. While the de-

fective diode is easy to find, the capacitor may show no visible damage.

### Switching Power Supplies

Switching power supplies are quite different than conventional supplies. In a "switcher," a switching transistor is used to change dc voltage levels. They usually have AF oscillators and complex feedback paths. Any component failure in the rectifiers, switch, feedback path or load usually results in a completely dead supply. Every part is suspect. While active device failure is still the number one suspect, it pays to carefully test all components if a diagnosis cannot be made with traditional techniques.

Some equipment, notably TVs and monitors, derive some of the power-supply voltages from the proper operation of other parts of the circuit. In the case of a TV or monitor, voltages are often derived by adding secondary low-voltage windings to the flyback transformer and rectifying the resultant ac voltage (usually about 15 kHz). These voltages will be missing if there is any problem with the circuit they are derived from.

### Amplifiers

Amplifiers are the most common circuits in electronics. The output of an ideal amplifier would match the input signal in every respect except magnitude: No distortion or noise would be added. Real amplifiers always add noise and distortion.

### Gain

Gain is the measure of amplification. Gain is usually expressed in decibels (dB) over a specified frequency range, known as the bandwidth or passband of the ampli-

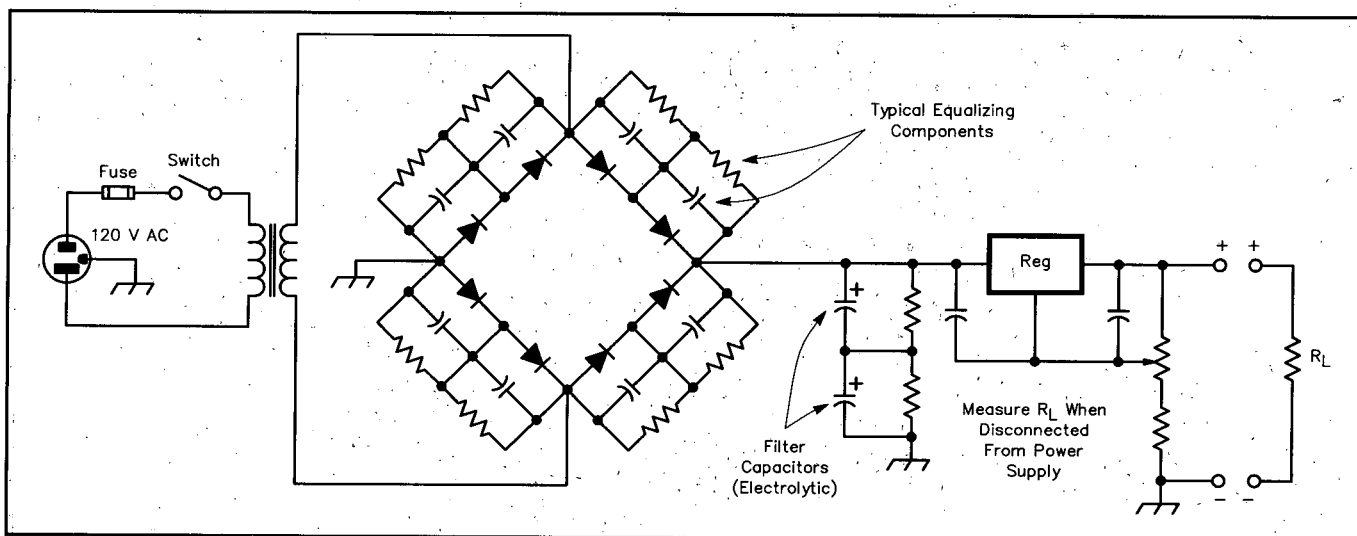

Fig 27.13 — Schematic of a typical power supply showing the components mentioned in the text.

fier. When an amplifier is used to provide a stable load for the preceding stage, or as an impedance transformer, there may be little or no voltage gain.

Amplifier failure usually results in a loss of gain or excessive distortion at the amplifier output. In either case, check external connections first. Is there power to the stage? Has the fuse opened? Check the speaker and leads in audio output stages, the microphone and push-to-talk (PTT) line in transmitter audio sections. Excess voltage, excess current or thermal runaway can cause sudden failure of semiconductors. The failure may appear as either a short, or open, circuit of one or more PN junctions.

Thermal runaway occurs most often in bipolar transistor circuits. If degenerative feedback (the emitter resistor reduces

base-emitter voltage as conduction increases) is insufficient, thermal runaway will allow excessive current flow and device failure. Check transistors by substitution, if possible.

Faulty coupling components can reduce amplifier output. Look for component failures that would increase series, or decrease shunt, impedance in the coupling network. Coupling faults can be located by signal tracing or parts substitution. Other passive component defects reduce amplifier output by shifting bias or causing active-device failure. These failures are evident when the dc operating voltages are measured.

In a receiver, a fault in the AGC loop may force a transistor into cutoff or saturation. Open the AGC line to the device and substitute a variable voltage for the AGC signal. If amplifier action varies with voltage, suspect the AGC-circuit components; otherwise, suspect the amplifier.

In an operating amplifier, check carefully for oscillations or noise. Oscillations are most likely to start with maximum gain and the amplifier input shorted. Any noise that is induced by 60-Hz sources can be heard, or seen with a 'scope synchronized to the ac line.

Unwanted amplifier RF oscillations should be cured with changes of lead dress or circuit components. Separate input leads from output leads; use coaxial cable to carry RF between stages; neutralize interelement or junction capacitance. Ferrite beads on the control element of the active device often stop unwanted oscillations.

Low-frequency oscillations ("motor-boating") indicate poor stage isolation or inadequate power-supply filtering. Try a better lead-dress arrangement and/or check the capacitance of the decoupling network (see Fig 27.14). Use larger capacitors at the power-supply leads; increase the number of capacitors or use separate decoupling capacitors at each stage. Coupling capacitors that are too low in value can also cause poor low-frequency response. Poor response to high frequencies is usually caused by circuit design.

### Amplifiers vs Switches

To help you hone your skills, let's analyze a few simple circuits. There is often a big difference in the performance of similar-looking circuits. Consider the differences between a common-emitter amplifier and a common-emitter switch circuit.

### Common-Emitter Amplifier

Fig 27.15 is a schematic of a common-emitter transistor amplifier. The emitter,

base and collector leads are labeled e, b and c, respectively. Important dc voltages are measured at these points and designated  $V_e$ ,  $V_b$  and  $V_c$ . Similarly, the important currents are  $I_e$ ,  $I_b$  and  $I_c$ .  $V+$  indicates the supply voltage.

First, analyze the voltages and signal levels in this circuit. The "junction drop," is the potential measured across a semiconductor junction that is conducting. It is typically 0.6 V for silicon and 0.2 V for germanium transistors.

This is a Class-A linear circuit. In Class-A circuits, the transistor is always conducting some current. R1 and R2 form a voltage divider that supplies dc bias ( $V_b$ ) for the transistor. Normally,  $V_e$  is equal to  $V_b$  less the emitter-base junction drop. R4 provides degenerative dc bias, while C3 provides a low-impedance path for the signal. From this information, normal operating voltages can be estimated.

The bias and voltages will be set up so that the transistor collector voltage,  $V_c$ , is somewhere between  $V+$  and ground potential. A good rule of thumb is that  $V_c$  should be about 0.5  $V+$ , although this can vary quite a bit, depending on component tolerances. The emitter voltage is usually a small percentage of  $V_c$ , say about 10%.

Any circuit failure that changes  $I_c$  (ranging from a shorted transistor or a failure in the bias circuit) changes  $V_c$  and  $V_e$  as well. An increase of  $I_c$  lowers  $V_c$  and raises  $V_e$ . If the transistor shorts from collector to emitter,  $V_c$  drops to about 1.2 V, as determined by the voltage divider formed by R3 and R4.

You would see nearly the same effect if the transistor were biased into saturation by collector-to-base leakage, a reduction in R1's value or an increase in R2's value. All of these circuit failures have the same effect. In some cases, a short in C1 or C2 could cause the same symptoms.

To properly diagnose the specific cause of low  $V_c$ , consider and test all of these parts. It is even more complex; an increase in R3's value would also decrease  $V_c$ . There would be one valuable clue, however; if R3 increased in value,  $I_c$  would not increase;  $V_e$  would also be low.

Anything that decreases  $I_c$  increases  $V_c$ . If the transistor failed "open," R1 increased in value, R2 were shorted to ground or R4 opened, then  $V_c$  would be high.

### Common-Emitter Switch

A common-emitter transistor switching circuit is shown in Fig 27.16. This circuit functions differently than the circuit shown in Fig 27.15. A linear amplifier is designed so that the output signal is a faithful reproduction of the input signal. Its

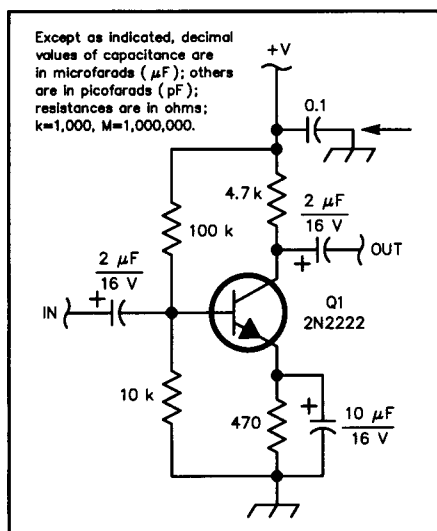

Fig 27.14 — The decoupling capacitor in this circuit is designated with an arrow.

Fig 27.15 — A typical common-emitter audio amplifier.

input and output may have any value from  $V_+$  to ground.

The switching circuit of Fig 27.16, however, is similar to a “digital” circuit. The active device is either on or off, 1 or 0, just like digital logic. Its input signal level should either be 0 V or positive enough to switch the transistor on fully (saturate). Its output state should be either full off (with no current flowing through the relay), or full on (with the relay energized). A voltmeter placed on the collector will show either approximately +12 V or 0 V, depending on the input.

Understanding this difference in operation is crucial to troubleshooting the two circuits. If  $V_c$  were +12 V in the circuit in Fig 27.15, it would indicate a circuit failure. A  $V_c$  of +12 V in the switching circuit, is normal when  $V_b$  is 0 V. (If  $V_b$  measured 0.8 V or higher,  $V_c$  should be low and the relay energized.)

### DC Coupled Amplifiers

In dc coupled amplifiers, the transistors are directly connected together without coupling capacitors. They comprise a unique troubleshooting case. Most often, when one device fails, it destroys one or more other semiconductors in the circuit. If you don't find all of the bad parts, the remaining defective parts can cause the installed replacements to fail immediately. To reliably troubleshoot a dc coupled circuit, you must test every semiconductor in the circuit and replace them all at once.

### Oscillators

In many circuits, a failure of the oscillator will result in complete circuit failure. A transmitter will not transmit, and a superheterodyne receiver will not receive if you have an internal oscillator failure. (These symptoms do not always mean oscillator failure, however.)

Whenever there is weakening or complete loss of signal from a radio, check oscillator operation and frequency. There are several methods:

- Use a receiver with a coaxial probe to listen for the oscillator signal.
- A dip meter can be used to check oscillators. In the absorptive mode, tune the dip meter to within  $\pm 15$  kHz of the oscillator, couple it to the circuit, and listen for a beat note in the dip-meter headphones.
- Look at the oscillator waveform on a scope. The operating frequency can't be determined with great accuracy, but you can see if the oscillator is working at all. Use a low capacitance (10 $\times$ ) probe for oscillator observations.
- Tube oscillators usually have negative

grid bias when oscillating. Use a high-impedance voltmeter to measure grid bias. The bias also changes slightly with frequency.

- Emitter current varies slightly with frequency in transistor oscillators. Use a sensitive, high-impedance voltmeter across the emitter resistor to observe the current level. (You can use Ohm's Law to calculate the current value.)

Many modern oscillators are phase-locked loops (PLLs). A PLL is a marriage of an analog oscillator and digital control circuitry. Read the Digital Circuitry section in this chapter and the **Oscillators** chapter of this book in order to learn PLL repair techniques.

To test for a failed oscillator tuned with inductors and capacitors, use a dip meter in the active mode. Set the dip meter to the oscillator frequency and couple it to the oscillator output circuit. If the oscillator is dead, the dip-meter signal will take its place and temporarily restore some semblance of normal operation. Tune the dip meter very slowly, or you may pass stations so quickly that they sound like “birdies.”

### Stability

We are spoiled; modern amateur equipment is very stable. Drift of several kilohertz per hour was once normal. You may want to modify old equipment for more stability, but drift that is consistent with the equipment design is not a defect. (This applies to new equipment as well as old.) It is normal for some digital displays to flash back and forth between two values for the least-significant digit.

Drift is caused by variations in the oscillator. Poor voltage regulation and heat are the most common culprits. Check regulation with a voltmeter (use one that is not affected by RF). Voltage regulators are usually part of the oscillator circuit. Check them by substitution.

Chirp is a form of rapid drift that is usually caused by excessive oscillator loading or poor power-supply regulation. The most common cause of chirp is poor design. If chirp appears suddenly in a working circuit, look for component or design defects in the oscillator or its buffer amplifiers. (For example, a shorted coupling capacitor increases loading drastically.) Also check lead dress, tubes and switches for new feedback paths (feedback defeats buffer action).

Frequency instability may also result from defects in feedback components. Too much feedback may produce spurious signals, while too little makes oscillator startup unreliable.

Sudden frequency changes are fre-

Fig 27.16 — A typical common-emitter switching amplifier.

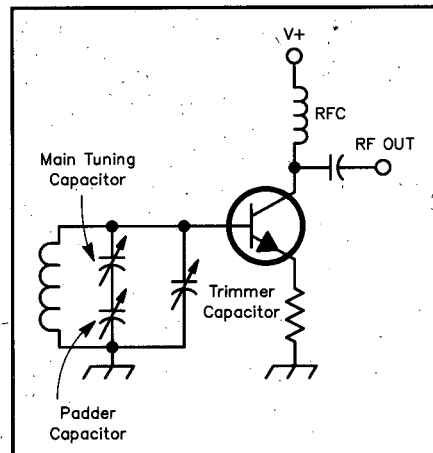

Fig 27.17 — A partial schematic of a simple oscillator showing the locations of the trimmer and padder capacitors.

quently the result of physical variations. Loose components or connections are probable causes. Check for arcing or dirt on printed-circuit boards, trimmers and variable capacitors, loose switch contacts, bad solder joints or loose connectors.

### Frequency Accuracy

Dial tracking errors may be associated with oscillator operation. Misadjustments in the frequency-determining components make dial accuracy worse at the ends of the dial. Tracking errors that are constant everywhere in the passband can be caused by misalignment or by slippage in the dial drive mechanism or indicator. This is usually cured by calibration of a simple mechanical adjustment.

In LC oscillators, tracking at the high-frequency end of the dial is controlled by trimmer capacitors. A trimmer is a variable capacitor connected in parallel with the main tuning capacitor (see Fig 27.17). The trimmer represents a higher percentage of the total capacitance at the high end of the tuning range. It has

relatively little effect on tuning characteristics at the low-frequency end of the dial.

Low-end tracking is adjusted by a padder capacitor. A padder is a variable capacitor that is connected in series with the main tuning capacitor. Padder capacitance has a greater effect at the low-frequency end of the dial. The padder capacitor is often eliminated to save money. In that case, the low-frequency

tracking is adjusted by the main tuning coil.

### Control Circuitry

Semiconductors have made it practical to use diodes for switching, running only a dc lead to the switching point. This eliminates problems caused by long analog leads in the circuit. Semiconductor switching usually reduces the cost and complexity of switching components. Switching

speed is increased; contact corrosion and breakage are eliminated. In exchange, troubleshooting is complicated by additional components such as voltage regulators and decoupling capacitors (see Fig 27.18). The technician must consider many more components and symptoms when working with diode and transistor switched circuits.

Mechanical switches are relatively rugged. They can withstand substantial voltage and current surges. The environment does not drastically affect them, and there is usually visible damage when they fail. Semiconductor switching offers inexpensive, high-speed operation. When subjected to excess voltage or current, however, most transistors and diodes silently expire. Occasionally, if the troubleshooter is lucky, one sends up a smoke signal to mark its passing.

Temperature changes semiconductor characteristics. A normally adequate control signal may not be effective when transistor beta is lowered by a cold environment. Heat may cause a control voltage regulator to produce an improper control signal.

A control signal is actually a bias for the semiconductor switch. Forward biased diodes and transistors act as closed switches; reverse biased components simulate open switches. If the control (bias) signal is not strong enough to completely saturate the semiconductor, conduction may not continue through a full ac cycle. Severe distortion can be the result.

When dc control leads provide unwanted feedback paths, switching transistors may become modulators or mixers. Additionally, any reverse biased semiconductor junction is a potential source of white noise.

### Microprocessor Control

Nearly every new transceiver is controlled by a miniature computer. Entire books have been written about microprocessor ( $\mu P$ ) control. Many of the techniques are discussed in the Digital Circuitry section. The **Digital** chapter of this book will also help you troubleshoot a  $\mu P$  problem. Many such problems end up back at the factory for service, however; the surface mounted components are just too difficult for most hams to replace. For successful repair of microprocessor controlled circuits, you should have the knowledge and test equipment necessary for computer repair. Familiarity with machine-language programming may also be desirable.

### Digital Circuitry

The digital revolution has hit most ham

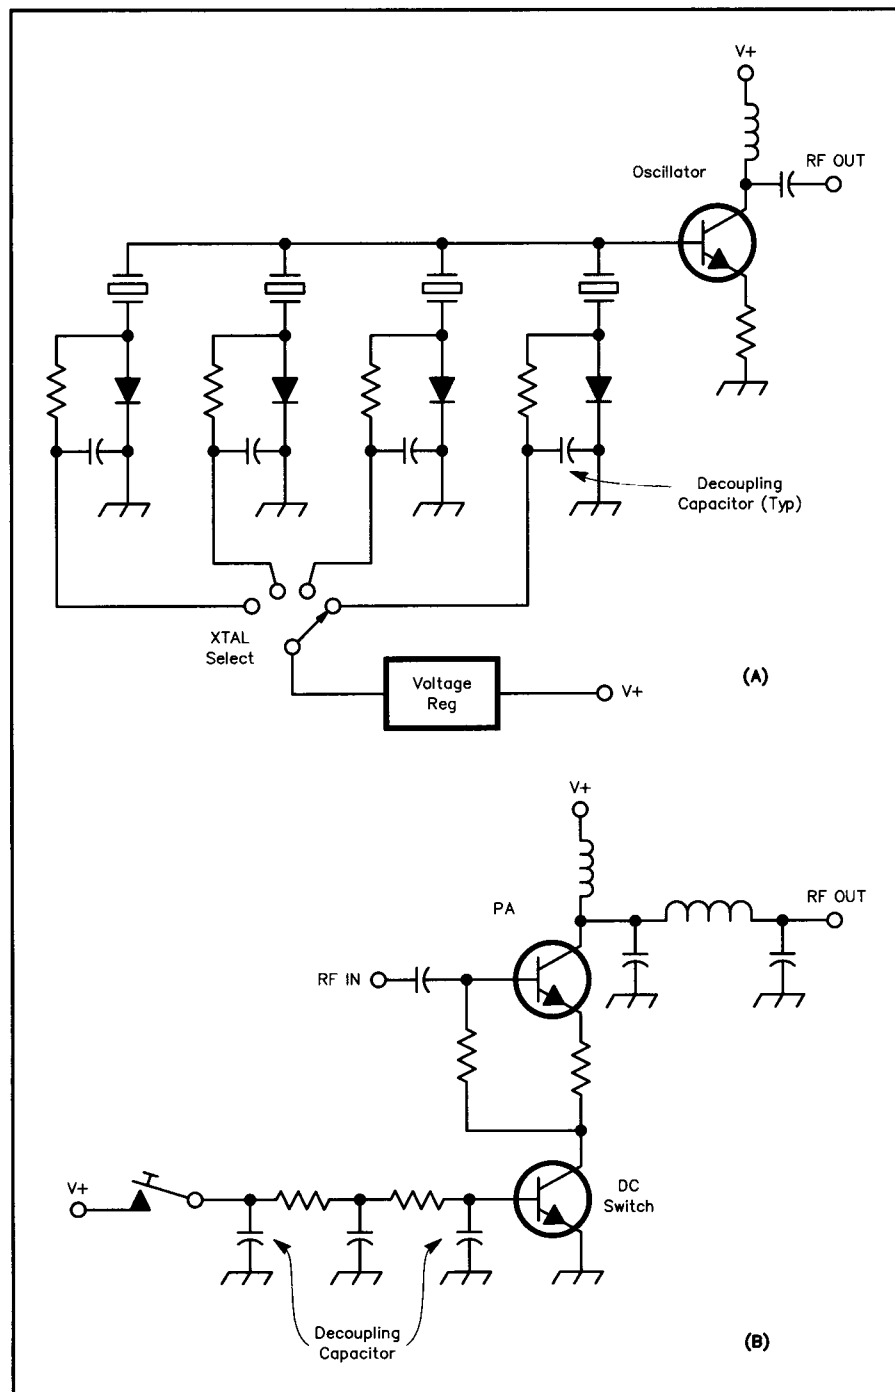

Fig 27.18 — Diode switching selects oscillator crystals at A. A transistor switch is used to key a power amplifier at B.

shacks and amateur equipment. Microprocessors have brought automation to everything from desk clocks to ham transceivers and computer controlled EME antenna arrays. Although every aspect of their operation may be resolved to a simple 1 or 0, or tristate (an infinite impedance or open circuit), the symptoms of their failure are far more complicated. As with other equipment:

- Observe the operating characteristics.
- Study the block diagram and the schematic.
- Test.
- Replace defective parts.

Problems in digital circuits have two elementary causes. First, the circuit may give false counts because of electrical noise at the input. Second, the gates may lock in one state.

False counts from noise are especially likely in a ham shack. (A 15- to 20- $\mu$ s voltage spike can trigger a TTL flip-flop.) Amateur Radio equipment often switches heavy loads; the attendant transients can follow the ac line or radiate directly to nearby digital equipment. Oscillation in the digital circuit can also produce false counts.

How these false counts affect a circuit is dependent on the design. A station clock may run fast, but a microprocessor controlled transceiver may "decide" that it is only a receiver. It might even be difficult to determine that there is a problem without a logic analyzer or a multitrace oscilloscope and a thorough understanding of circuit operation.

Begin by removing the suspect equipment from RF fields. If the symptoms stop when there is no RF energy around, you need to shield the equipment from RF.

In the mid '90s, microprocessors in general use clock speeds up to a few hundred megahertz. (They are increasing all the time.) It may be impossible to filter RF signals from the lines when the RF is near the clock frequency. In these cases, the best approach is to shield the digital circuit and all lines running to it.

If digital circuitry interferes with other nearby equipment, it may be radiating spurious signals. These signals can interfere with your Amateur Radio operation or other services. Digital circuitry can also be subject to interference from strong RF fields. Erratic operation or a complete "lock up" is often the result. The ARRL book, *Radio Frequency Interference: How to Find It and Fix It* has a chapter on computer and digital interference. That chapter discusses interference to and from digital devices and circuits.

### Logic Levels

To troubleshoot a digital circuit, check for the correct voltages at the pins of each chip. The correct voltages may not always be known, but you should be able to identify the power pins ( $V_{cc}$  and ground).

The voltages on the other pins should be either a logic high, a logic low, or tristate (more on this later). In most working digital circuitry the logic levels are constantly changing, often at RF rates. A dc voltmeter may not give reliable readings. An oscilloscope or logic analyzer is usually needed to troubleshoot digital circuitry.

Most digital circuit failures are caused by a failed logic IC. In clocked circuits, listen for the clock signal with a coax probe and a suitable receiver. If the signal is found at the clock chip, trace it to each of the other ICs to be sure that the clock system is intact. Some digital circuits use VHF clock speeds; an oscilloscope must have a bandwidth of at least twice the clock speed to be useful. If you have a suitable scope, check the pulse timing and duration against circuit specifications.

As in most circuits, failures are catastrophic. It is unlikely that an AND gate will suddenly start functioning like an OR gate. It is more likely that the gate will have a signal at its input, and no signal at the output. In a failed device, the output pin will have a steady voltage. In some cases, the voltage is steady because one of the input signals is missing. Look carefully at what is going into a digital IC to determine what should be coming out. Keep manufacturers' data books handy. These data books describe the proper functioning of most digital devices.

### Tristate Devices

Many digital devices are designed with a third logic state, commonly called tristate. In this state, the output of the device acts as if it weren't there at all. Many such devices can be connected to a common "bus," with the devices that are active at any given time selected by software or hardware control signals. A computer's data and address busses are good examples of this. If any one device on the bus fails by locking itself on in a 0 or 1 logic state, the entire bus becomes nonfunctional. These tristate devices can be locked "on" by inherent failure or a failure of the signal that controls them.

### Simple Gate Tests

Logic gates, flip-flops and counters can be tested (see Fig 27.19) by triggering them manually, with a power supply (4 to 5 V is a safe level). Diodes may be checked with an ohmmeter. Testing of more complicated ICs requires the use of a logic

analyzer, multitrace scope or a dedicated IC tester.

## TROUBLESHOOTING HINTS

### Receivers

A receiver can be diagnosed using any of the methods described earlier, but if there is not even a faint sound from the speaker, signal injection is not a good technique. If you lack troubleshooting experience, avoid following instinctive hunches. That leaves signal tracing as the best method.

The important characteristics of a receiver are selectivity, sensitivity, stability and fidelity. Receiver malfunctions ordinarily affect one or more of these areas.

### Selectivity

Tuned transformers or the components used in filter circuits may develop a shorted turn, capacitors can fail and alignment is required occasionally. Such defects are accompanied by a loss of sensitivity. Except in cases of catastrophic failure (where either the filter passes all signals, or none), it is difficult to spot a loss of selectivity. Bandwidth and insertion-loss measurements are necessary to judge filter performance.

### Sensitivity

A gradual loss of sensitivity results from gradual degradation of an active device or long-term changes in component values. Sudden partial sensitivity changes are usually the result of a component failure, usually in the RF or IF stages. Complete and sudden loss of sensitivity is caused by an open circuit anywhere in the signal path or by a "dead" oscillator.

### Receiver Stability

The stability of a receiver depends on its oscillators. See the Oscillators section elsewhere in this chapter.

**Fig 27.19** — This simple digital circuit can be tested with a few components. In this case, an AND gate is tested. Open and close S1 and S2 while comparing the voltmeter reading with a truth table for the device.

## Distortion

Receiver distortion may be the effect of poor connections or faulty components in the signal path. AGC circuits produce many receiver defects that appear as distortion or insensitivity.

## AGC

AGC failure usually causes distortion that affects only strong signals. All stages operate at maximum gain when the AGC influence is removed. An S meter can help diagnose AGC failure because it is operated by the AGC loop.

An open AGC bypass capacitor causes feedback through the loop. This often results in a receiver "squeal" (oscillation). Changes in the loop time constant affect tuning. If stations consistently blast, or are too weak for a brief time when first tuned in, the time constant is too fast. An excessively slow time constant makes tuning difficult, and stations fade after tuning. If the AGC is functioning, but the "timing" seems wrong, check the large-value capacitors found in the AGC circuit — they usually set the AGC time constants. If the AGC is not functioning, check the AGC-detector circuit. There is often an AGC voltage that is used to control several stages. A failure in any one stage could affect the entire loop.

## Detector Problems

Detector trouble usually appears as

complete loss or distortion of the received signal. AM, SSB and CW signals may be weak and unintelligible. FM signals will sound distorted. Look for an open circuit in the detector near the detector diodes. If tests of the detector parts indicate no trouble, look for a poor connection in the power-supply or ground lead. A BFO that is "dead" or off frequency prevents SSB and CW reception. In modern rigs, the BFO frequency is either crystal controlled, or derived from the PLL.

## Receiver Alignment

Unfortunately, IF transformers are as enticing to the neophyte technician as a carburetor is to a shade-tree mechanic. In truth, radio alignment (and for that matter, carburetor repair) is seldom required. Circuit alignment may be justified under the following conditions:

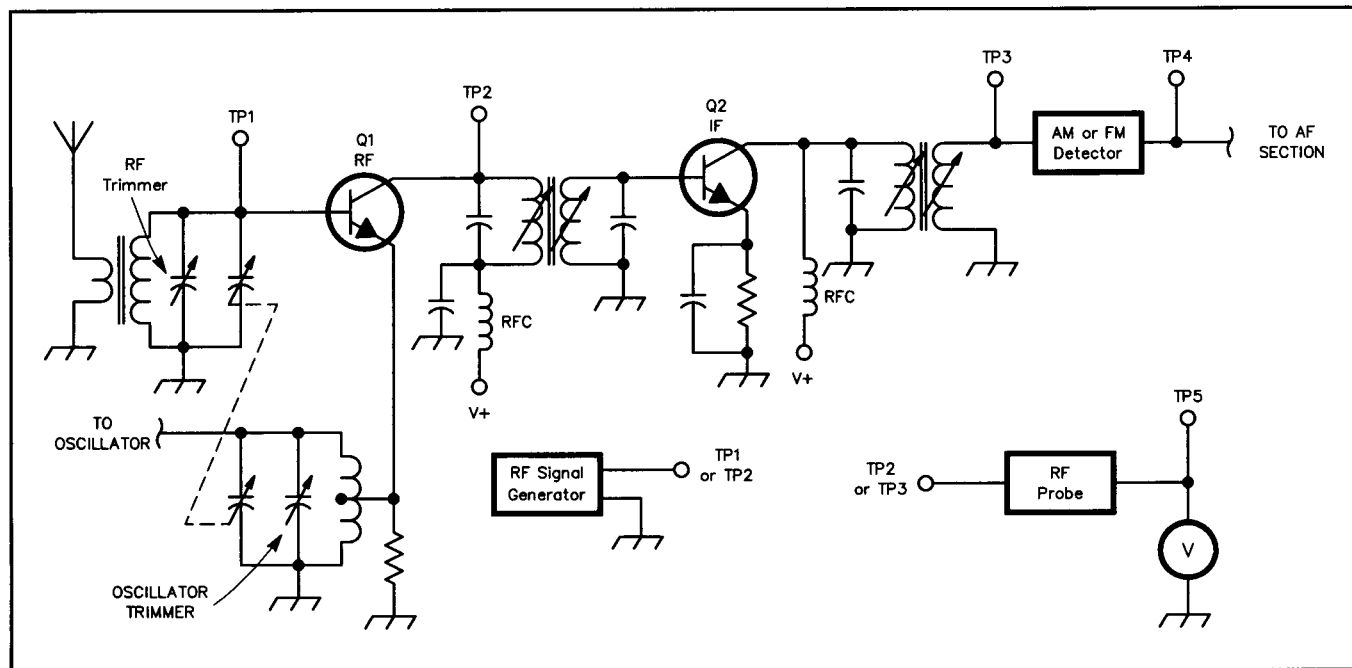

- The set is very old and has not been adjusted in many years.
- The circuit has been subject to abusive treatment or environment.
- There is obvious misalignment from a previous repair.
- Tuned-circuit components or crystals have been replaced.
- An inexperienced technician attempted alignment without proper equipment. ("But all the screws in those little metal cans were loose!")
- There is a malfunction, but all other circuit conditions are normal. (Faulty trans-

formers can be located because they will not tune.)

Even if one of the above conditions is met, do not attempt alignment unless you have the proper equipment. Receiver alignment should progress from the detector to the antenna terminals. When working on an FM receiver, align the detector first, then the IF and limiter stages and finally the RF amplifier and local oscillator stages. For an AM receiver, align the IF stages first, then the RF amplifier and oscillator stages.

Both AM and FM receivers can be aligned in much the same manner. Always follow the manufacturer's recommended alignment procedure. If one is not available, follow these guidelines:

1. Set the receiver RF gain to maximum, BFO control to zero or center (if applicable to your receiver) and tune to the high end of the receiver passband.
2. Disable the AGC.
3. Set the signal source to the center of the IF passband, with no modulation and minimum signal level.
4. Connect the signal source to the input of the IF section.
5. Connect a voltmeter to the IF output as shown in **Fig 27.20**.
6. Adjust the signal-source level for a slight indication on the voltmeter.
7. Peak each IF transformer in order, from the meter to the signal source. The adjustments interact; repeat steps 6 and 7

**Fig 27.20** — Typical receiver alignment test points. To align the entire radio, connect a dc voltmeter at TP4. Inject an IF signal at TP2 and adjust the IF transformers. Move the signal generator to TP1 and inject an RF signal for alignment of the RF amplifier and oscillator stages. To align a single stage, place the generator at the input and an RF voltmeter (or demodulator probe and dc voltmeter) at the output: TP1/TP2 for RF, TP2/TP3 for IF.

until adjustment brings no noticeable improvement.

8. Remove the signal source from the IF-section input, reduce the level to minimum, set the frequency to that shown on the receiver dial and connect the source to the antenna terminals. If necessary, tune around for the signal — if the local oscillator is not tracking, it may be off.

9. Adjust the signal level to give a slight reading on the voltmeter.

10. Adjust the trimmer capacitor of the RF amplifier for a peak reading of the test signal. (Verify that you are reading the correct signal by switching the source on and off.)

11. Reset the signal source and the receiver tuning for the low end of the passband.

12. Adjust the local-oscillator padder for peak reading.

13. Steps 8 through 11 interact, so repeat them until the results are as good as you can get them.

## Transmitters

Many potential transmitter faults are discussed in several different places in this chapter. There are, however, a few techniques used to ensure stable operation of RF amplifiers in transmitters that are not covered elsewhere.

High-power RF amplifiers often use parasitic chokes to prevent instability. Older parasitic chokes usually consist of a 51- to 100- $\Omega$  noninductive resistor with a coil wound around the body and connected to the leads. It is used to prevent VHF and UHF oscillations in a vacuum-tube amplifier. The suppressor is placed in the plate lead, close to the plate connection.

In recent years, problems with this style of suppressor have been discovered. Look at the **Amplifiers** chapter for information about suppressing parasitics.

Parasitic chokes often fail from excessive current flow. In these cases, the resistor is charred. Occasionally, physical shock or corrosion produces an open circuit in the coil. Test for continuity with an ohmmeter.

Transistor amplifiers are protected against parasitic oscillations by low-value resistors or ferrite beads in the base or collector leads. Resistors are used only at low power levels (about 0.5 W), and both methods work best when applied to the base lead. Negative feedback is used to prevent oscillations at lower frequencies. An open component in the feedback loop may cause low-frequency oscillation, especially in broadband amplifiers.

## Keying

The simplest form of modulation is

on/off keying. Although it may seem that there cannot be much trouble with such an elementary form of modulation, two very important transmitter faults are the result of keying problems.

Key clicks are produced by fast rise and decay times of the keying waveform. Most transmitters include components in the keying circuitry to prevent clicks. When clicks are experienced, check the keying filter components first, then the succeeding stages. An improperly biased power amplifier, or a Class C amplifier that is not keyed, may produce key clicks even though the keying waveform earlier in the circuit is correct. Clicks caused by a linear amplifier may be a sign of low-frequency parasitic oscillations. If they occur in an amplifier, suspect insufficient power-supply decoupling. Check the power-supply filter capacitors and all bypass capacitors.

The other modulation problem associated with on/off keying is called backwave. Backwave is a condition in which the signal is heard, at a reduced level, even when the key is up. This occurs when the oscillator signal feeds through a keyed amplifier. This usually indicates a design flaw, although in some cases a component failure or improper keyed-stage neutralization may be to blame.

## Low Output Power

Some transmitters automatically reduce power in the TUNE mode. Check the owner's manual to see if the condition is normal. Check the control settings. Transmitters that use broadband amplifiers require so little effort from the operator that control settings are seldom noticed. The CARRIER (or DRIVE) control may have been bumped. Remember to adjust tuned amplifiers after a significant change in operating frequency (usually 50 to 100 kHz). Most modern transmitters are designed to reduce power if there is high (say 2:1) SWR. Check these obvious external problems before you tear apart your rig.

Power transistors may fail if the SWR protection circuit malfunctions. Such failures occur at the "weak link" in the amplifier chain: It is possible for the drivers to fail without damaging the finals. An open circuit in the "reflected" side of the sensing circuit leaves the transistors unprotected, a short "shuts them down."

Low power output in a transmitter may also spring from a misadjusted carrier oscillator or a defective SWR protection circuit. If the carrier oscillator is set to a frequency well outside the transmitter passband, there may be no measurable output. Output power will increase

steadily as the frequency is moved into the passband.

## Transceivers

### Switching

Elaborate switching schemes are used in transceivers for signal control. Many transceiver malfunctions can be attributed to relay or switching problems. Suspect the switching controls when:

- The S meter is inoperative, but the unit otherwise functions. (This could also be a bad S meter.)
- There is arcing in the tank circuit. (This could also be caused by a bad antenna system.)
- Plate current is high during reception.
- There is excessive broadband PA noise in the receiver.

Since transceiver circuits are shared, stage defects frequently affect both the transmit and receive modes, although the symptoms may change with mode. Oscillator problems usually affect both transmit and receive modes, but different oscillators, or frequencies, may be used for different emissions. Check the block diagram.

For example, one particular transceiver uses a single carrier oscillator with three different crystals (see **Fig 27.21**). One crystal sets the carrier frequency for CW, AM and FSK transmit. Another sets USB transmit and USB/CW receive, and a third sets LSB transmit and LSB/FSK receive. This radio showed a strange symptom. After several hours of CW operation, the receiver produced only a light hiss on USB and CW. Reception was good in other modes, and the power meter showed full output during CW transmission. An examination of the block diagram and schematic showed that only one of the crystals (and seven support components) was capable of causing the problem.

## VOX

Voice operated transmit (VOX) controls are another potential trouble area. If there is difficulty in switching to transmit in the VOX mode, check the VOX-SENSITIVITY and ANTI-VOX control settings. Next, see if the PTT and manual (MOX) transmitter controls work. If the PTT and MOX controls function, examine the VOX control diodes and amplifiers. Test the switches, control lines and control voltage if the transmitter does not respond to other TR controls.

VOX SENSITIVITY and ANTI-VOX settings should also be checked if the transmitter switches on in response to received audio. Suspect the ANTI-VOX circuitry next.

Unacceptable VOX timing results from a poor VOX-delay adjustment, or a bad resistor or capacitor in the timing circuit or VOX amplifiers.

### Alignment

The mixing scheme of the modern SSB transceiver is complicated. The signal passes through many mixers, oscillators and filters. Satisfactory SSB communication requires accurate adjustment of each stage. Do not attempt any alignment without a copy of the manufacturer's instructions and the necessary test equipment.

### Troubleshooting Charts

Tables 27.2 through 27.5 list some common problems and possible cures. These tables are not all-inclusive. They are a collection of hints and shortcuts that may save you some troubleshooting time. If you don't find your problem listed, continue with systematic troubleshooting.

### COMPONENTS

Once you locate a defective part, it is time to select a replacement. This is not

always an easy task. Each electronic component has a function. This section acquaints you with the functions, failure modes and test procedures of resistors, capacitors, inductors and other components. Test the components implicated by symptoms and stage-level testing. In most cases, a particular faulty component will be located by these tests. If a faulty component is not indicated, check the circuit adjustments. As a last resort, use a shotgun approach — replace all parts in the problem area with components that are known to be good.

### Check the Circuit

Before you install a replacement component of any type, you should be sure that another circuit defect didn't cause the failure. Check the circuit voltages carefully before installing any new component. Check the potential on each trace to the bad component. The old part may have "died" as a result of a lethal voltage. Measure twice — repair once! (With apologies to the old carpenter.) Of course, circuit performance is the final test of any substitution.

### Fuses

Most of the time, when a fuse fails, it is for a reason — usually a short circuit in the load. A fuse that has failed because of a short circuit usually shows the evidence of high current: a blackened interior with little blobs of fuse element everywhere. Fuses can also fail by fracturing the element at either end. This kind of failure is not visible by looking at the fuse. Check even "good" fuses with an ohmmeter. You may save hours of troubleshooting.

For safety reasons, always use *exact* replacement fuses. Check the current and voltage ratings. The fuse timing (fast, normal or slow blow) must be the same as the original. Never attempt to force a fuse that is not the right size into a fuse holder. The substitution of a bar, wire or penny for a fuse invites a "smoke party."

### Wires

Wires seldom fail unless abused. Short circuits can be caused by physical damage to insulation or by conductive contamination. Damaged insulation is usually apparent during a close visual inspection of the conductor or connector. Look carefully

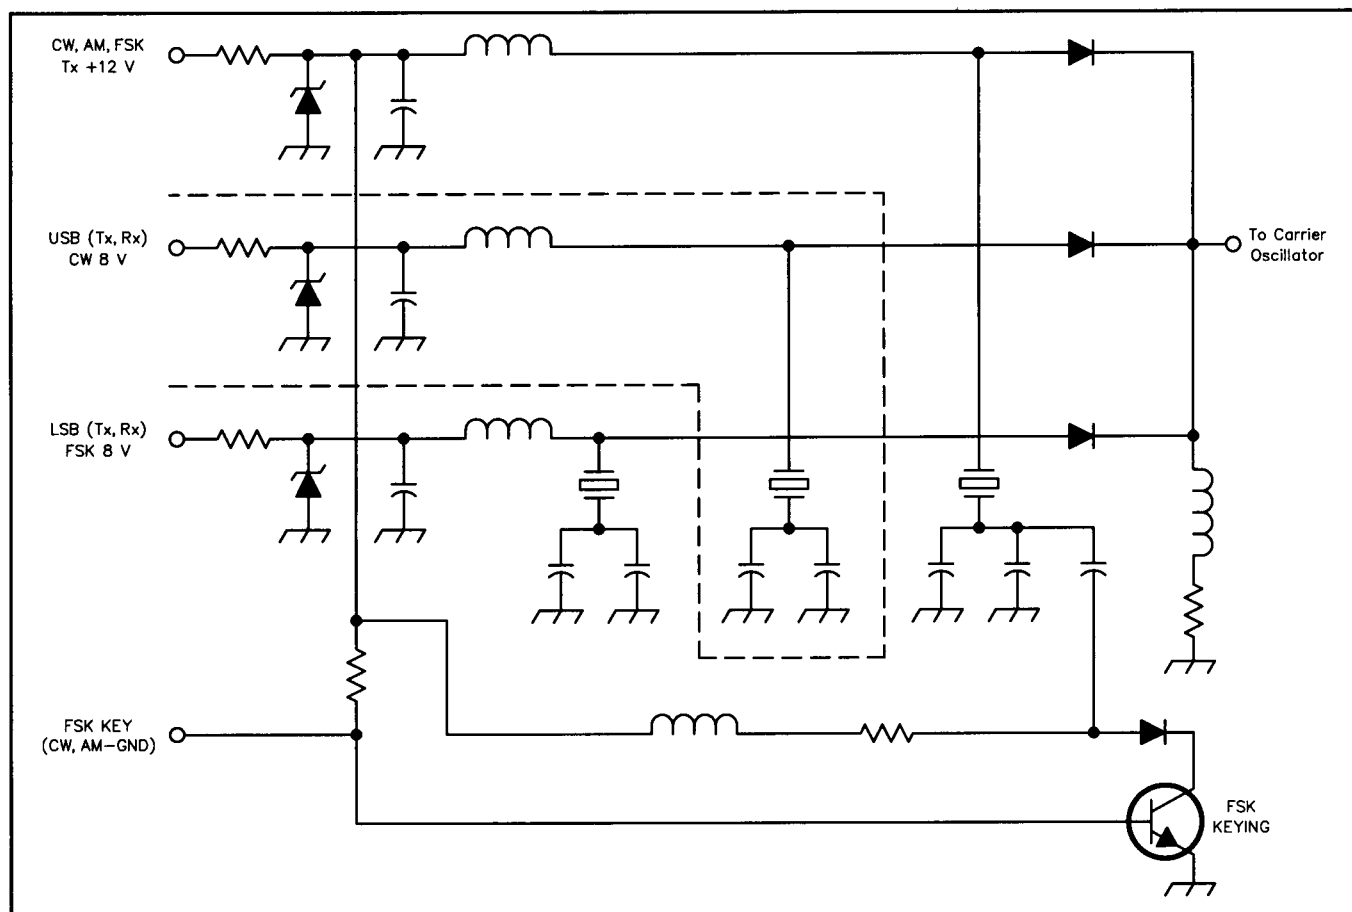

Fig 27.21 — Partial schematic of a transceiver oscillator. The symptoms described in the text are caused by one or more components inside the dashed lines or a faulty USB/CW control signal.

where conductors come close to corners or sharp objects. Repair worn insulation by replacing the wire or securing an insulating sleeve (spaghetti) or heat-shrink tubing over the worn area.

When wires fail, the failure is usually caused by stress and flexing. Nearly everyone has broken a wire by bending it back and forth, and broken wires are usually easy to detect. Look for sharp bends or bulges in the insulation.

When replacing conductors, use the same material and size, if possible. Substitute only wire of greater cross-sectional area (smaller gauge number) or material of greater conductivity. Insulated wire should be rated at the same, or higher, temperature and voltage as the wire it replaces.

### Connectors

Connection faults are one of the most common failures in electronic equipment. This can range from something as simple as the ac-line cord coming out of the wall, to a connector having been put on the wrong socket, to a defective IC socket. Connectors that are plugged and unplugged frequently can wear out, becoming intermittent or noisy. Check connectors carefully when troubleshooting.

Connector failure can be hard to detect. Most connectors maintain contact as a result of spring tension that forces two conductors together. As the parts age, they become brittle and lose tension. Any connection may deteriorate because of non-conductive corrosion at the contacts. Solder helps prevent this problem but even soldered joints suffer from corrosion when exposed to weather.

The dissipated power in a defective connector usually increases. Signs of excess heat are sometimes seen near poor connections in circuits that carry moderate current. Check for short and open circuits with an ohmmeter or continuity tester. Clean those connections that fail as a result of contamination.

Occasionally, corroded connectors may be repaired by cleaning, but replacement of the conductor/connector is usually required. Solder all connections that may be subject to harsh environments and protect them with acrylic enamel, RTV compound or a similar coating.

Choose replacement connectors with consideration of voltage and current ratings. Use connectors with symmetrical pin arrangements only where correct insertion will not result in a safety hazard or circuit damage.

### Resistors

Resistors usually fail by becoming an open circuit. More rarely they change

value. This is usually caused by excess heat. Such heat may come from external sources or from power dissipated within the resistor. Sufficient heat burns the re-

**Table 27.2**

### Symptoms and Their Causes for All Electronic Equipment

<i>Symptom</i>	<i>Cause</i>
<b>Power Supplies</b>	
No output voltage	Open circuit (usually a fuse or transformer winding)
Hum or ripple	Faulty regulator, capacitor or rectifier, low-frequency oscillation
<b>Amplifiers</b>	
Low gain	Transistor, coupling capacitors, emitter-bypass capacitor, AGC component, alignment
Noise	Transistors, coupling capacitors, resistors
Oscillations	Dirt on variable capacitor or chassis, shorted op-amp input
Untuned (oscillations do not change with frequency)	Audio stages
Tuned	RF, IF and mixer stages
Squeal	Open AGC-bypass capacitor
Static-like crashes	Arcing trimmer capacitors, poor connections
Static in FM receiver	Faulty limiter stage, open capacitor in ratio detector, weak RF stage, weak incoming signal
Intermittent noise	All components and connections, band-switch contacts, potentiometers (especially in dc circuits), trimmer capacitors, poor antenna connections
Distortion (constant)	Oscillation, overload, faulty AGC, leaky transistor, open lead in tab-mount transistor, dirty potentiometer, leaky coupling capacitor, open bypass capacitors, imbalance in tuned FM detector, IF oscillations, RF feedback (cables)
Distortion (strong signals only)	Open AGC line, open AGC diode
Frequency change	Physical or electrical variations, dirty or faulty variable capacitor, broken switch, loose compartment parts, poor voltage regulation, oscillator tuning (trouble when switching bands)
<b>No Signals</b>	
All bands	Dead VFO or heterodyne oscillator, PLL won't lock
One band only	Defective crystal, oscillator out of tune, band switch
No function control	Faulty switch, poor connection, defective switching diode or circuit
<b>Improper Dial Tracking</b>	
Constant error across dial	Dial drive
Error grows worse along dial	Circuit adjustment

**Table 27.3**

### Transmitter Problems

<i>Symptom</i>	<i>Cause</i>
Key clicks	Keying filter, distortion in stages after keying
<b>Modulation Problems</b>	
Loss of modulation	Broken cable (microphone, PTT, power), open circuit in audio chain, defective modulator
Distortion on transmit	Defective microphone, RF feedback from lead dress, modulator imbalance, bypass capacitor, improper bias, excessive drive
Arcing	Dampness, dirt, improper lead dress
Low output	Incorrect control settings, improper carrier shift (CW signal outside of passband) audio oscillator failure, transistor or tube failure, SWR protection circuit
<b>Antenna Problems</b>	
Poor SWR	Damaged antenna element, matching network, feed line, balun failure (see below), resonant conductor near antenna, poor connection at antenna
Balun failure	Excessive SWR, weather or cold-flow damage in coil choke, broken wire
RFI	Arcing or poor connections anywhere in antenna system or nearby conductors

sistor until it becomes an open circuit.

Resistors can also fracture and become an open circuit as a result of physical shock. Contamination of a high-value resistor (100 k $\Omega$  or more) can cause a change in value through leakage. This contamination can occur on the resistor body, mounts or printed-circuit board. Resistors that have changed value should be replaced. Leakage is cured by cleaning the resistor body and surrounding area.

In addition to the problems of fixed-value resistors, potentiometers and rheostats can develop noise problems, especially in dc circuits. Dirt often causes intermittent contact between the wiper and resistive element. To cure the problem, spray electronic contact cleaner into the control, through holes in the case, and rotate the shaft a few times.

The resistive element in wire-wound potentiometers eventually wears and breaks from the sliding action of the wiper. In this case, the control needs to be replaced.

Replacement resistors should be of the same value, tolerance, type and power rating as the original. The value should stay within tolerance. Replacement resis-

tors may be of a different type than the original, if the characteristics of the replacement are consistent with circuit requirements.

Substitute resistors can usually have a greater power rating than the original, except in high-power emitter circuits where the resistor also acts as a fuse or in cases where the larger size presents a problem.

Variable resistors should be replaced with the same kind (carbon or wire wound) and taper (linear, log, reverse log and so on) as the original. Keep the same, or better tolerance and pay attention to the power rating.

In all cases, mount high-temperature resistors away from heat-sensitive components. Keep carbon resistors away from heat sources. This will extend their life and ensure minimum resistance variations.

## Capacitors

Capacitors usually fail by shorting, opening or becoming electrically (or physically) leaky. They rarely change value. Capacitor failure is usually caused by excess current, voltage, temperature or age. Leakage can be external to the ca-

pacitor (contamination on the capacitor body or circuit) or internal to the capacitor.

## Tests

The easiest way to test capacitors is out of circuit with an ohmmeter. In this test, the resistance of the meter forms a timing circuit with the capacitor to be checked. Capacitors from 0.01  $\mu\text{F}$  to a few hundred  $\mu\text{F}$  can be tested with common ohmmeters. Set the meter to its highest range and connect the test leads across the discharged capacitor. When the leads are connected, current begins to flow. The capacitor passes current easily when discharged, but less easily as the charge builds. This shows on the meter as a low resistance that builds, over time, toward infinity.

The speed of the resistance build-up corresponds to capacitance. Small capacitance values approach infinite resistance almost instantly. A 0.01- $\mu\text{F}$  capacitor checked with an 11-M $\Omega$  FETVOM would increase from zero to a two-thirds scale reading in 0.11 s, while a 1- $\mu\text{F}$  unit would require 11 s to reach the same reading. If the tested capacitor does not reach infinity within five times the period taken to reach the two-thirds point, it has excess leakage. If the meter reads infinite resistance immediately, the capacitor is open. (Aluminum electrolytics normally exhibit high-leakage readings.)

Fig 27.22 shows a circuit that may be used to test capacitors. To use this circuit, make sure that the power supply is off, set S1 to CHARGE and S2 to TEST, then connect the capacitor to the circuit. Switch on the power supply and allow the capacitor to charge until the voltmeter reading stabilizes. Next, switch S1 to TEST and watch the meter for a few seconds. If the capacitor is good, the meter will show no potential. Any appreciable voltage indicates excess leakage. After testing, set S1 to CHARGE, switch off the power supply, and press the DISCHARGE button until the meter shows 0 V, then remove the capacitor from the test circuit.

Capacitance can also be measured with a capacitance meter, an RX bridge or a dip meter. Some DMMs (digital multimeters) measure capacitance. Capacitance measurements made with DMMs and dedicated capacitance meters are much more accurate than those made with RX bridges or dip meters. To determine capacitance with a dip meter, a parallel-resonant circuit should be constructed using the capacitor of unknown value and an inductor of known value. The formula for resonance is discussed in the AC Theory chapter of this book.

Table 27.4

### Receiver Problems

Symptom	Cause
Low sensitivity	Semiconductor contamination, weak tube, alignment
Signals and calibrator heard weakly (low S-meter readings)	RF chain
(strong S-meter readings)	AF chain, detector
No signals or calibrator heard, only hissing	RF oscillators
<b>Distortion</b>	
On strong signals only	AGC fault
AGC fault	Active device cut off or saturated
Difficult tuning	AGC fault
Inability to receive	Detector fault
AM weak and distorted	Poor detector, power or ground connection
CW/SSB unintelligible	BFO off frequency or dead
FM distorted	Open detector diode

Table 27.5

### Transceiver Problems

Symptom	Cause
Inoperative S meter	Faulty relay
PA noise in receiver	
Excessive current on receive	
Arcing in PA	
Reduced signal strength on transmit and receive	IF failure
Poor VOX operation	VOX amplifiers and diodes
Poor VOX timing	Adjustment, component failure in VOX timing circuits or amplifiers
VOX consistently tripped by receiver audio	AntiVOX circuits or adjustment

It is best to keep a collection of known components that have been measured on accurate L or C meters. Alternatively, a "standard" value can be obtained by ordering 1 or 2% components from an electronics supplier. A 10%-tolerance component can be used as a standard; however, the results will only be known to within 10%. The accuracy of tests made with any of these alternatives depends on the accuracy of the "standard" value component. Further information on this technique appears in Bartlett's article, "Calculating Component Values," in Nov 1978 *QST*.

### Cleaning

The only variety of common capacitor that can be repaired is the air-dielectric variable capacitor. Electrical connection to the moving plates is made through a spring-wiper arrangement (see Fig 27.23). Dirt normally builds on the contact area, and they need occasional cleaning. Before cleaning the wiper/contact, use gentle air pressure and a soft brush to remove all dust and dirt from the capacitor plates. Apply some electronic contact cleaning fluid. Rotate the shaft quickly several times to work in the fluid and establish contact. Use the cleaning fluid sparingly, and keep it off the plates except at the contact point.

### Replacements

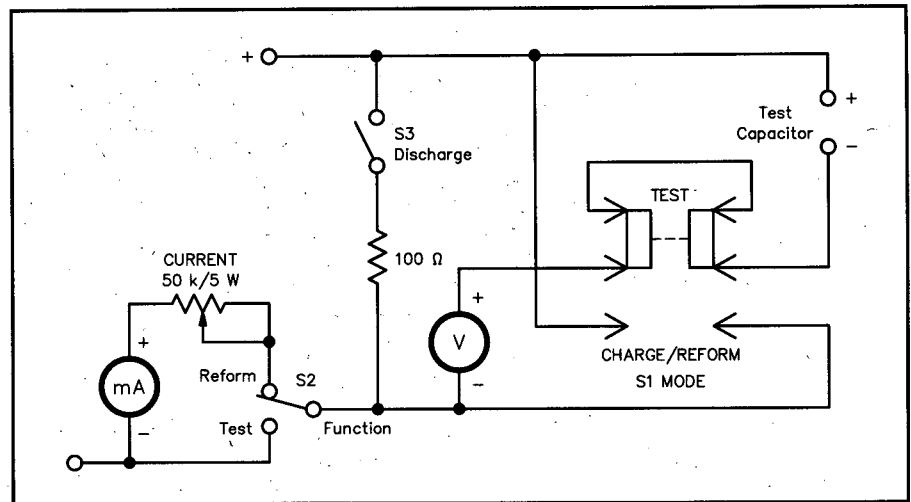

Replacement capacitors should match the original in value, tolerance, dielectric, working voltage and temperature coefficient. Use only ac-rated capacitors for line service. If exact replacements are not available, substitutes may vary from the original part in the following respects: Bypass capacitors may vary from one to three times the capacitance of the original. Coupling capacitors may vary from one half to twice the value of the original. Capacitance values in tuned circuits (especially filters) must be exact. (Even then, any replacement will probably require circuit realignment.)

If the same kind of capacitor is not available, use one with better dielectric characteristics. Do not substitute polarized capacitors for nonpolarized parts. Capacitors with a higher working voltage may be used, although the capacitance of an electrolytic capacitor used significantly below its working voltage will usually increase with time.

The characteristics of each type of capacitor are discussed in the **Real World Components** chapter. Consider these characteristics if you're not using an exact replacement capacitor.

### Inductors and Transformers

The most common inductor or trans-

**Fig 27.22 — A fixture for testing capacitors and reformation the dielectric of electrolytic capacitors. Use 12 V for testing the capacitor. Use the capacitor working voltage for dielectric reformation.**

former failure is a broken conductor. More rarely, a short circuit can occur across one or more turns of a coil. In an inductor, this changes the value. In a transformer, the turns ratio and resultant output voltage changes. In high-power circuits, excessive inductor current can generate enough heat to melt plastics used as coil forms.

Inductors may be checked for open circuit failure with an ohmmeter. In a good inductor, dc resistance rarely exceeds a few ohms. Shorted turn and other changes in inductance show only during alignment or inductance measurement.

The procedure for measurement of inductance with a dip meter is the same as that given for capacitance measurement, except that a capacitor of known value is used in the resonant circuit.

Replacement inductors must have the same inductance as the original, but that is only the first requirement. They must also carry the same current, withstand the same voltage and present nearly the same Q as the original part. Given the original as a pattern, the amateur can duplicate these qualities for many inductors. Note that inductors with ferrite or iron-powder cores are frequency sensitive, so the replacement must have the same core material.

If the coil is of simple construction, with the form and core undamaged, carefully count and write down the number of turns and their placement on the form. Also note how the coil leads are arranged and connected to the circuit. Then determine the wire size and insulation used. Wire diameter, insulation and turn spacing are critical to the current and voltage ratings of an inductor. (There is little hope of matching coil characteristics unless the wire is duplicated exactly in the new part.) Next,

**Fig 27.23 — Partial view of an air-dielectric variable capacitor. If the capacitor is noisy or erratic in operation, apply electronic cleaning fluid where the wiper contacts the rotor plates.**

remove the old winding (be careful not to damage the form) and apply a new winding in its place. Be sure to dress all coil leads and connections in exactly the same manner as the original. Apply Q dope to hold the finished winding in place.

Follow the same procedure in cases where the form or core is damaged, except that a suitable replacement form or core (same dimensions and permeability) must be found.

Ready-made inductors may be used as replacements if the characteristics of the original and the replacement are known and compatible. Unfortunately, many inductors are poorly marked. If so, some comparisons, measurements and circuit analysis are usually necessary.

When selecting a replacement inductor, you can usually eliminate parts that bear no physical resemblance to the original part. This may seem odd, but the Q of an inductor depends on its physical dimensions and the permeabil-

ity of the core material. Inductors of the same value, but of vastly different size or shape, will likely have a great difference in  $Q$ . The  $Q$  of the new inductor can be checked by installing it in the circuit, aligning the stage and performing the manufacturer's passband tests. Although this practice is all right in a pinch, it does not yield an accurate  $Q$  measurement. Methods to measure  $Q$  appear in the **Test Procedures** chapter.

Once the replacement inductor is found, install it in the circuit. Duplicate the placement, orientation and wiring of the original. Ground-lead length and arrangement should not be changed. Isolation and magnetic shielding can be improved by replacing solenoid inductors with toroids. If you do, however, it is likely that many circuit adjustments will be needed to compensate for reduced coupling and mutual inductance. Alignment is usually required whenever a tuned-circuit component is replaced.

A transformer consists of two inductors that are magnetically coupled. Transformers are used to change voltage and current levels (this changes impedance also). Failure usually occurs as an open circuit or short circuit of one or more windings.

Amateur testing of power transformers is limited to ohmmeter tests for open circuits and voltmeter checks of secondary voltage. Make sure that the power-line voltage is correct, then check the secondary voltage against that specified. There should be less than 10% difference between open-circuit and full-load secondary voltage.

Replacement transformers must match the original in voltage, volt-ampere (VA), duty cycle and operating-frequency ratings. They must also be compatible in size. (All transformer windings should be

insulated for the full power-supply voltage.)

## Relays

Although relays have been replaced by semiconductor switching in low-power circuits, they are still used extensively in high-power Amateur Radio equipment. Relay action may become sluggish. AC relays can buzz (with adjustment becoming impossible). A binding armature or weak springs can cause intermittent switching. Excessive use or hot switching ruins contacts and shortens relay life.

You can test relays with a voltmeter by jumpering across contacts with a test lead (power on, in circuit) or with an ohmmeter (out of circuit). Look for erratic readings across the contacts, open or short circuits at contacts or an open circuit at the coil.

Most failures of simple relays can be repaired by a thorough cleaning. Clean the contacts and mechanical parts with a residue-free cleaner. Keep it away from the coil and plastic parts that may be damaged. Dry the contacts with lint-free paper, such as a business card; then burnish them with a smooth steel blade. Do not use a file to clean contacts.

Replacement relays should match or exceed the original specifications for voltage, current, switching time and stray impedance (impedance is significant in RF circuits only). Many relays used in transceivers are specially made for the manufacturer. Substitutes may not be available from any other source.

Before replacing a multicontact relay, make a drawing of the relay, its position, the leads and their routings through the surrounding parts. This drawing allows you to complete the installation properly, even if you are distracted in the middle of the operation.

## Semiconductors

### Diodes

The primary function of a diode is to pass current in one direction only. They can be easily tested with an ohmmeter.

**Signal or switching diodes** — The most common diode in electronics equipment, they are used to convert ac to dc, to detect RF signals or to take the place of relays to switch ac or dc signals within a circuit. Signal diodes usually fail open, although shorted diodes are not rare. They can easily be tested with an ohmmeter.

**Power-rectifier diodes** — Most equipment contains a power supply, so power-rectifier diodes are the second-most common diodes in electronic circuitry. They usually fail shorted, blowing the power-supply fuse.

**Other diodes** — Zener diodes are made with a predictable reverse-breakdown voltage and used as voltage regulators. Varactor diodes are specially made for use as voltage controlled variable capacitors. (Any semiconductor diode may be used as a voltage-variable capacitance, but the value will not be as predictable as that of a varactor.) A Diac is a special-purpose diode that passes only pulses of current in each direction.

**Diode tests** — There are several basic tests for most diodes. First, is it a diode? Does it conduct in one direction and block current flow in the other? An ohmmeter is suitable for this test in most cases. An ohmmeter will read high resistance in one direction, low resistance in the other. Make sure the meter uses a voltage of more than 0.7 V and less than 1.5 V to measure resistance. Use a good diode to determine the meter polarity.

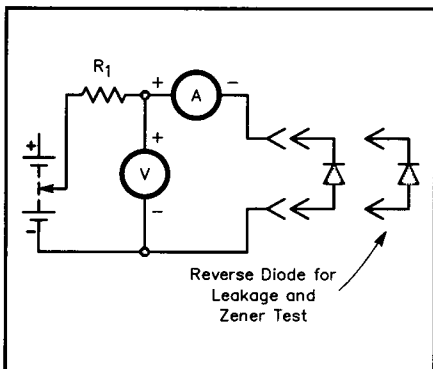

Diodes should be tested out of circuit. Disconnect one lead of the diode from the circuit, then measure the forward and reverse resistance. Diode quality is shown by the ratio of reverse to forward resistance. A ratio of 100:1 or greater is common for signal diodes. The ratio may go as low as 10:1 for old power diodes.

The first test is a forward-resistance test. Set the meter to read  $\times 100$  and connect the test probes across the diode. When the negative terminal of the ohmmeter battery is connected to the cathode, the meter will typically show about 200 to 300  $\Omega$  (forward resistance) for a good silicon diode, 200 to 400  $\Omega$  for a good germanium diode. The exact value varies quite a bit from one meter to the next.

Next, test the reverse resistance. Reverse the lead polarity and set the meter to  $\times 1M$  (times one million, or the highest scale available on the meter) to measure diode reverse resistance. Good diodes should show 100 to 1000 M $\Omega$  for silicon and 100 k $\Omega$  to 1 M $\Omega$  for germanium. When you are done, mark the meter lead polarity for future reference.

This procedure measures the junction resistances at low voltage. It is not useful to test Zener diodes. A good Zener diode will not conduct in the reverse direction at voltages below its rating.

We can also test diodes by measuring the voltage drop across the diode junction while the diode is conducting. (A test circuit is shown in Fig 27.24.) To test, connect the diode, adjust the supply voltage until the current through the diode matches the manufacturer's specification and compare the junction drop to that specified. Silicon junctions usually show about 0.6 V, while germanium is typically 0.2 V. Junction voltage-drop increases with cur-

**Fig 27.24 — A diode conduction, leakage and Zener-point test fixture. The ammeter should read mA for conduction and Zener point,  $\mu A$  for leakage tests.**

rent flow. This test can be used to match diodes with respect to forward resistance at a given current level.

A final simple diode test measures leakage current. Place the diode in the circuit described above, but with reverse polarity. Set the specified reverse voltage and read the leakage current on a milliammeter. (The currents and voltages measured in the junction voltage-drop and leakage tests vary by several orders of magnitude.)

The most important specification of a Zener diode is the Zener (or avalanche) voltage. The Zener-voltage test also uses the circuit of Fig 27.24. Connect the diode in reverse. Set the voltage to minimum, then gradually increase it. You should read low current in the reverse mode, until the Zener point is reached. Once the device begins to conduct in the reverse direction, the current should increase dramatically. The voltage shown on the voltmeter is the Zener point of the diode. If a Zener diode has become leaky, it might show in the leakage-current measurement, but substitution is the only dependable test.

**Replacement diodes** — When a diode fails, check associated components as well. Replacement rectifier diodes should have the same current and peak inverse voltage (PIV) as the original. Series diode combinations are often used in high-voltage rectifiers, with resistor and capacitor networks to distribute the voltage equally among the diodes.

Switching diodes may be replaced with diodes that have equal or greater current ratings and a PIV greater than twice the peak-to-peak voltage encountered in the circuit. Switching time requirements are not critical except in RF, logic and some keying circuits. Logic circuits may require exact replacements to assure compatible switching speeds and load characteristics. RF switching diodes used near resonant circuits must have exact replacements as the diode resistance and capacitance will affect the tuned circuit.

Voltage, current and capacitance characteristics must be considered when replacing varactor diodes. Once again, exact replacements are best. Zener diodes should be replaced with parts having the same Zener voltage and equal or better current, power, impedance and tolerance specifications. Check the associated current-limiting resistor when replacing a Zener diode.

### Bipolar Transistors

Transistors are primarily used to switch or amplify signals. Transistor failures occur as an open junction, a shorted junction, excess leakage or a change in ampli-

fication performance.

Most transistor failure is catastrophic. A transistor that has no leakage and amplifies at dc or audio frequencies will usually perform well over its design range. For this reason, transistor tests need not be performed at the planned operating frequency. Tests are made at dc or a low frequency (usually 1000 Hz). The circuit under repair is the best test of a potential replacement part. Swapping in a replacement transistor in a failed circuit will often result in a cure.

A simple and reliable bipolar-transistor test can be performed with the transistor in a circuit and the power on. It requires a test lead, a 10-k $\Omega$  resistor and a voltmeter. Connect the voltmeter across the emitter/collector leads and read the voltage. Then use the test lead to connect the base and emitter (Fig 27.25A). Under these conditions, conduction of a good transistor will be cut off and the meter should show nearly the entire supply voltage across the emitter/collector leads. Next, remove the clip lead and connect the 10-k $\Omega$  resistor from the base to the collector. This should bias the transistor into conduction and the emitter/collector voltage should drop (Fig 27.25B). (This test indicates transistor response to changes in bias voltage.)

Transistors can be tested (out of circuit) with an ohmmeter in the same manner as diodes. Look up the device characteristics before testing and consider the consequences of the ohmmeter-transistor circuit. Limit junction current to 1 to 5 mA for small-signal transistors. Transistor destruction or inaccurate measurements may result from careless testing.

Use the  $\times 100\ \Omega$  and  $\times 1000\text{-}\Omega$  ranges for small-signal transistors. For high-power transistors use the  $\times 1\ \Omega$  and  $\times 10\text{-}\Omega$  ranges. The reverse-to-forward resistance ratio for good transistors may vary from 30:1 to better than 1000:1.

Germanium transistors sometimes show high leakage when tested with an ohmmeter. Bipolar transistor leakage may be specified from the collector to the base, emitter to base or emitter to collector (with the junction reverse biased in all cases). The specification may be identified as  $I_{cbo}$ ,  $I_{bo}$ , collector cutoff current or collector leakage for the base-collector junction,  $I_{cbo}$ , and so on for other junctions.<sup>3</sup> Leak-

<sup>3</sup>The term " $I_{cbo}$ " means "Current from collector to base with emitter open." The subscript notation indicates the status of the three device terminals. The terminals measured are listed first, with the remaining terminal listed as "s" (shorted) or "o" (open).

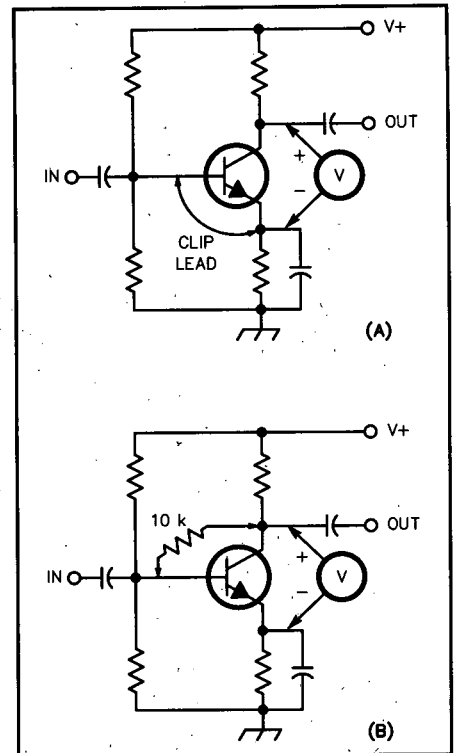

Fig 27.25 — An in-circuit semiconductor test with a clip lead, resistor and voltmeter. The meter should read  $V_+$  at (A). During test (B) the meter should show a decrease in voltage, ranging from a slight variation down to a few millivolts. It will typically cut the voltage to about half of its initial value.

Fig 27.26 — A test circuit for measuring collector-base leakage with the emitter shorted to ground, open or connected to ground through a variable resistance, depending on the setting of  $S_1$ . See the transistor manufacturer's instructions for test conditions and the setting of  $R_1$  (if used). Reverse battery polarity for PNP transistors.

age current increases with junction temperature.

A suitable test fixture for base-collector leakage measurements is shown in Fig 27.26. Make the required connections and

set the voltage as stated in the transistor specifications and compare the measured leakage current with that specified. Small-signal germanium transistors exhibit  $I_{cbo}$

**Fig 27.27 — A test circuit for measuring transistor beta. Values for R1 and R2 are dependent on the current range of the transistor tested. Reverse the battery polarity for PNP transistors.**

**Fig 27.28 — Ohmmeter tests of a JFET. The junction is reverse biased at A and forward biased at B.**

and  $I_{ebo}$  leakage currents of about 15  $\mu A$ . Leakage increases to 90  $\mu A$  or more in high-power components. Leakage currents for silicon transistors are seldom more than 1  $\mu A$ . Leakage current tends to double for every 10°C increase above 25°C.

Breakdown-voltage tests actually measure leakage at a specified voltage, rather than true breakdown voltage. Breakdown voltage is known as  $BV_{cbo}$ ,  $BV_{ces}$  or  $BV_{ceo}$ . Use the same test fixture shown for leakage tests, adjust the power supply until the specified leakage current flows, and compare the junction voltage against that specified.

A circuit to measure dc current gain is shown in **Fig 27.27**. Transistor gain can range from 10 to over 1000 because it is not usually well controlled during manufacture. Gain of the active device is not critical in a well-designed transistor circuit.

The test conditions for transistor testing are specified by the manufacturer. When testing, do not exceed the voltage, current (especially in the base circuit) or dissipated-power rating of the transistor. Make sure that the load resistor is capable of dissipating the power generated in the test.

While these simple test circuits will identify most transistor problems, RF devices should be tested at RF. Most component manufacturers include a test-circuit schematic on the data sheet. The test circuit is usually an RF amplifier that operates near the high end of the device frequency range.

Semiconductor failure is sometimes the result of environmental conditions. Open junctions, excess leakage (except with germanium transistors) and changes in amplification performance result from overload or excessive current. Electrostatic discharge can destroy a semiconductor in microseconds. Shorted junctions are caused by voltage spikes. Check surrounding parts for the cause of the transistor's demise, and correct the problem before installing a replacement.

### JFETs

Junction FETs can be tested with an ohmmeter in much the same way as bipolar transistors (see text and **Fig 27.28**). Reverse leakage should be several megohms or more. Forward resistance should be 500 to 1000  $\Omega$ .

### MOSFETs

MOS (metal-oxide semiconductor) layers are extremely fragile. Normal body static is enough to damage them. Even "gate protected" (a diode is placed across the MOS layer to clamp voltage)

MOSFETs may be destroyed by a few volts of static electricity.

Make sure the power is off, capacitors discharged and the leads of a MOSFET are shorted together before installing or removing it from a circuit. Use a voltmeter to be sure the chassis is near ground potential, then touch the chassis before and during MOSFET installation and removal. This assures that there is no difference of potential between your body, the chassis and the MOSFET leads. Ground the soldering-iron tip with a clip lead when soldering MOS devices. The FET source should be the first lead connected to and the last disconnected from a circuit. The insulating layers in MOSFETs prevent testing with an ohmmeter. Substitution is the only practical means for amateur testing of MOSFETs.

### FET Considerations

Replacement FETs should be of the same kind as the original part: JFET or MOSFET, P-channel or N-channel, enhancement or depletion. Consider the breakdown voltage required by the circuit. The breakdown voltage should be at least two to four times the power-supply and signal voltages in amplifiers. Allow for transients of ten times the line voltage in power supplies. Breakdown voltages are usually specified as  $V_{(BR)GSS}$  or  $V_{(BR)GDO}$ .

The gate-voltage specification gives the gate voltage required to cut off or initiate channel current (depending on the mode of operation). Gate voltages are usually listed as  $V_{GS(OFF)}$ ,  $V_p$  (pinch off),  $V_{TH}$  (threshold) or  $I_D(ON)$  or  $I_{TH}$ .

Dual-gate MOSFET characteristics are more complicated because of the interaction of the two gates. Cutoff voltage, breakdown voltage and gate leakage are the important traits of each gate.

### Integrated Circuits

The basics of integrated circuits are covered in earlier chapters of this book. Amateurs seldom have the sophisticated equipment required to test ICs. Even a multitrace 'scope can view only their simplest functions. We must be content to check every other possible cause, and only then assume that the problem lies with an IC. Experienced troubleshooters will tell you that — most of the time anyway — if a defective circuit uses an IC, it is the IC that is bad.

**Linear ICs** — There are two major classes of ICs: linear and digital. Linear ICs are best replaced with identical units. Original equipment manufacturers are the best source of a replacement; they are the only source with a reason to stockpile obsolete or custom-made items. If substi-

tution of an IC is unavoidable, first try the cross-reference guides published by several distributors. You can also look in manufacturers' databooks and compare pinouts and other specifications.

**Digital ICs** — It is usually not a good idea to substitute digital devices. While it may be okay to substitute an AB74LS00YZ from manufacturer "A" with a CD74LS00WX from a different manufacturer, you will usually not be able to replace an LS (low-power Schottky) device with an S (Schottky), C (CMOS) or any of a number of other families. The different families all have different speed, current-consumption, input and output characteristics. You would have to analyze the circuit to determine if you could substitute one type for another. The characteristics of various digital families are discussed in the **Digital** chapter.

### Semiconductor Substitution

In all cases try to obtain exact replacement semiconductors. Specifications vary slightly from one manufacturer to the next. Cross-reference equivalents are useful, but not infallible. Before using an equivalent, check the specifications against those for the original part. When choosing a replacement, consider:

- Is it silicon or germanium?
- Is it a PNP or an NPN?
- What are the operating frequency and input/output capacitance?
- How much power does it dissipate (often less than  $V_{max} \times I_{max}$ )?
- Will it fit the original mount?
- Are there unusual circuit demands (low noise and so on)?
- What is the frequency of operation?

Remember that cross-reference equivalents are not guaranteed to work in every application. There may be cases where two dissimilar devices have the same part number, so it pays to compare the listed replacement specifications with the intended use. If "the book" says to use a diode in place of an RF transistor, it isn't going to work! Derate power specifications, as recommended by the manufacturer, for high-temperature operation.

### Tubes

The most common tube failures in amateur service are caused by cathode depletion and gas contamination. Whenever a tube is operated, the coating on the cathode loses some of its ability to produce electrons. It is time to replace the tube when electron production (cathode current,  $I_c$ ) falls to 50 - 60% of that exhibited by a new tube.

Gas contamination in a tube can often

be identified easily because there may be a greenish or whitish-purple glow between the elements during operation. (A faint deep-purple glow is normal in most tubes.) The gas reduces tube resistance and leads to runaway plate current evidenced by a red glow from the anode, interelectrode arcing or a blown power-supply fuse. Less common tube failures include an open filament, broken envelope and interelectrode shorts.

The best test of a tube is to substitute a new one. Another alternative is a tube tester; these are now rare. You can also do some limited tests with an ohmmeter. Tube tests should be made out of circuit so circuit resistance does not confuse the results:

Use an ohmmeter to check for an open filament (remove the tube from the circuit first). A broken envelope is visually obvious, although a cracked envelope may appear as a gassy tube. Interelectrode shorts are evident during voltage checks on the operating stage. Any two elements that show the same voltage are probably shorted. (Remember that some interelectrode shorts, such as the cathode-suppressor grid, are normal.)

Generally, a tube may be replaced with another that has the same type number. Compare the data sheets of similar tubes to assess their compatibility. Consider the base configuration and pinout, interelectrode capacitances (a small variation is okay except for tubes in oscillator service), dissipated power ratings of the plate and screen grid and current limitations (both peak and average). For example, the 6146A may be replaced with a 6146B (heavy duty), but not vice versa.

In some cases, minor type-number differences signify differences in filament voltages, or even base styles, so check all specifications before making a replacement. (Even tubes of the same model number, prefix and suffix vary slightly, in some respects, from one supplier to the next.)

### AFTER THE REPAIRS

Once you have completed your troubleshooting and repairs, it is time to put the equipment back together. Take a little extra time to make sure you have done everything correctly.

### All Units

Give the entire unit a complete visual inspection. Look for any loose ends left over from your troubleshooting procedures — you may have left a few components temporarily soldered in place or overlooked some other repair error. Look for cold solder joints and signs of damage

incurred during the repair. Double check the position, leads and polarity of components that were removed or replaced.

Make sure that all ICs are properly oriented in their sockets and all of the pins are properly inserted in the IC socket or printed-circuit board holes. Test fuse continuity with an ohmmeter and verify that the current rating matches the circuit specification.

Look at the position of all of the wires and components. Make sure that wires and cables will be clear of hot components, screw points and other sharp edges. Make certain that the wires and components will not be in the way when covers are installed and the unit is put back together.

Separate the leads that carry dc, RF, input and output as much as possible. Plug-in circuit boards should be firmly seated with screws tightened and lock washers installed if so specified. Shields and ground straps should be installed just as they were on the original.

### For Transmitters Only

Since the signal produced by an HF transmitter can be heard the world over, a thorough check is necessary after any service has been performed. Do not exceed the transmitter duty cycle while testing. Limit transmissions to 10 to 20 seconds unless otherwise specified by the owner's manual.

1. Set all controls as specified in the operation manual, or at midscale.

2. Connect a dummy load and a power meter to the transmitter output.

3. Set the drive or carrier control for low output.

4. Switch the power on.

5. Transmit and quickly set the final-amplifier bias to specifications.

6. In narrowband equipment, slowly tune the output network through resonance. The current dip should be smooth and repeatable. It should occur simultaneously with the maximum power output. Any sudden jumps or wiggles of the current meter indicate that the amplifier is unstable. Adjust the neutralization circuit (according to the manufacturer's instructions) if one is present or check for oscillation. An amplifier usually requires neutralization whenever active devices, components or lead dress (that affect the output/input capacitance) are changed.

7. Check to see that the output power is consistent with the amplifier class used in the PA (efficiency should be about 25% for Class A, 50 to 60% for Class AB or B, and 70 to 75% for Class C).

8. Repeat steps 4 through 6 for each band of operation from lowest to highest frequency.

9. Check the carrier balance (in SSB transmitters only) and adjust for minimum power output with maximum RF drive and no microphone gain.

10. Adjust the VOX controls.

11. Measure the passband and distortion levels if equipment (wideband 'scope or spectrum analyzer) is available.

### Other Repaired Circuits

After the preliminary checks, set the circuit controls per the manufacturer's specifications (or to midrange if specifications are not available) and switch the power on. Watch and smell for smoke, and listen for odd sounds such as arcing or hum. Operate the circuit for a few minutes, consistent with allowable duty cycle. Verify that all operating controls function properly.

Check for intermittent connections by subjecting the circuit to heat, cold and slight flexure. Also, tap or jiggle the chassis lightly with an alignment tool or other insulator.

If the equipment is meant for mobile or portable service, operate it through an appropriate temperature range. Many mobile radios do not work on cold mornings, or on hot afternoons, because a temperature-dependent intermittent was not found during repairs.

### Button It Up

After you are convinced that you have repaired the circuit properly, put it all back together. If you followed the advice in this book, you have all the screws and assorted doodads in a secure container. Look at the notes you took while taking it apart; put it back together in the reverse order. Don't forget to reconnect all internal connections, such as ac-power, speaker or antenna leads.

Once the case is closed, and all appears well, don't neglect the final, important step — make sure it still works. Many an experienced technician has forgotten this important step, only to discover that some

minor error, such as a forgotten antenna connector, has left the equipment non-functional.

### PROFESSIONAL REPAIRS

This chapter does not tell you how to perform all repairs. Repairs that deal with very complex and temperamental circuits, or that require sophisticated test equipment, should be passed on to a professional.

The factory authorized service personnel have a lot of experience. What seems like a servicing nightmare to you is old hat to them. There is no one better qualified to service your equipment than the factory.

If the manufacturer is no longer in business, check with your local dealer or look in the classified ads in electronics and Amateur Radio magazines. You can usually find one or more companies that service "all makes and models." Your local TV shop might be willing to tackle a repair, especially if you have located a schematic.

If you are going to ship your equipment somewhere for repair, notify the repair center first. Get authorization for shipping and an identification name or number for the package.

### Packing It Up

You can always blame shipping damage on the shipper, but it is a lot easier for all concerned if you package your equipment properly for shipping in the first place. Firmly secure all heavy components, either by tying them down or blocking them off with shipping foam. Large vacuum tubes should be wrapped in packing material or shipped separately. Make sure that all circuit boards and parts are firmly attached.

Use a box within a box for shipping. (See Fig 27.29.) Place the equipment and some packing material inside a box and seal it with tape. Place that box inside another that is at least six inches larger in each dimension. Fill the gap with packing material, seal, address and mark the outer box. Choose a good freight carrier and insure the package.

Don't forget to enclose a statement of the trouble, a short history of operation and any test results that may help the service technician. Include a good description of the things you have tried. Be honest! At current repair rates you want to tell the technician everything to help ensure an efficient repair.

Even if you ended up sending it back to the factory, you can feel good about your experience. You learned a lot by trying,

and you have sent it back knowing that it really did require the services of a "pro." Each time you troubleshoot and repair a piece of electronic circuitry, you learn something new. The down side is that you may develop a reputation as a real electronics whiz. You may find yourself spending a lot of time at club meetings offering advice, or getting invited over to a lot of shacks for a late-evening pizza snack. There are worse fates.

## THE SCOPE OF THE PROBLEM

As our lives become filled with technology, the likelihood of electronic interference increases. Every lamp dimmer, garage-door opener or other new technical “toy” contributes to the electrical noise around us. Many of these devices also “listen” to that growing noise and may react unpredictably to their electronic neighbors.

Sooner or later, nearly every Amateur Radio operator will have a problem with interference. Most cases of interference can be cured! The proper use of “diplomacy” skills and standard cures will usually solve the problem.

This chapter, by Ed Hare, KA1CV, is only an overview. The ARRL RFI book, *Radio Frequency Interference: How to Find It and Fix It* contains detailed information on the causes of and cures for nearly every type of interference problem.<sup>1</sup>

## Important Terms

**Bypass capacitor** — a capacitor used to provide a low-impedance radio-frequency path around a circuit element.

**Common-mode signals** — signals that are in phase on both (or several) conductors in a system.

**Conducted signals** — signals that travel by electron flow in a wire or other conductor.

**Decibel (dB)** — a logarithmic unit of relative power measurement that ex-

presses the ratio of two power levels.

**Differential-mode signals** — Signals that arrive on two or more conductors such that there is a 180° phase difference between the signals on some of the conductors.

**Electromagnetic compatibility (EMC)** — the ability of electronic equipment to be operated without performance degradation from interference.

**Electromagnetic interference (EMI)** — any electrical disturbance that interferes with the normal operation of electronic equipment.

**Emission** — electromagnetic energy propagated from a source by radiation.

**Filter** — a network of resistors, inductors and/or capacitors that offer little resistance to certain frequencies while blocking or attenuating other frequencies.

**Fundamental overload** — interference resulting from the fundamental signal of a radio transmitter.

**Ground** — a low-impedance electrical connection to the earth. Also, a common reference point in electronic circuits.

**Harmonics** — signals at exact multiples of the operating (or *fundamental*) frequency.

**High-pass filter** — a filter designed to pass all frequencies above a cutoff frequency, while rejecting frequencies below the cutoff frequency.

**Induction** — the transfer of electrical signals via magnetic coupling.

**Interference** — the unwanted interaction between electronic systems.

**Intermodulation** — the undesired mixing of two or more frequencies in a nonlinear device, which produces additional frequencies.

**Low-pass filter** — a filter designed to pass all frequencies below a cutoff fre-

quency, while rejecting frequencies above the cutoff frequency.

**Noise** — any signal that interferes with the desired signal in electronic communications or systems.

**Nonlinear** — having an output that is not in linear proportion to the input.

**Notch filter** — a filter that rejects or suppresses a narrow band of frequencies within a wider band of frequencies.

**Passband** — the band of frequencies that a filter conducts with essentially no attenuation.

**Radiated emission** — radio-frequency energy that is coupled between two systems by electromagnetic fields.

**Radio-frequency interference (RFI)** — interference caused by a source of radio-frequency signals. This is a subclass of EMI.

**Spurious emission** — An emission, on frequencies outside the necessary bandwidth of a transmission, the level of which may be reduced without affecting the information being transmitted.

**Susceptibility** — the characteristic of electronic equipment that permits undesired responses when subjected to electromagnetic energy.

**TVI** — interference to television systems.

## Pieces of the Problem

Every interference problem has two components — the equipment that is involved and the people who use it. A solution requires that we deal with both the equipment and the people effectively.

First, define the term “interference” without emotion. The ARRL recommends that the hams and their neighbors cooperate to find solutions. This view is shared by the FCC.

<sup>1</sup>*Radio Frequency Interference — How to Find It and Fix It*, ISBN 0-87259-375-4, ARRL Order no. 3754, available from ARRL Publication Sales Department or your local Amateur Radio equipment dealer.

# Responsibility

When an interference problem occurs, we may ask “Who is to blame?” The ham and the neighbor often have different opinions. It is almost natural (but unproductive) to fix blame instead of the problem.

No amount of wishful thinking (or demands for the “other guy” to solve the problem) will result in a cure for interference. Each individual has a unique perspective on the situation, and a different degree of understanding of the personal and technical issues involved. On the other hand, each person has certain responsibilities to the other and should be prepared to address those responsibilities fairly.

## FCC Regulations

A radio operator is responsible for the proper operation of the radio station. This responsibility is spelled out clearly in Part 97 of the FCC regulations. If interference is caused by a spurious emission from your station, you *must* correct the problem there.

Fortunately, most cases of interference are *not* the fault of the transmitting station. Most interference problems involve some kind of electrical noise or fundamental overload.

## Personal Diplomacy

What happens when you first talk to your neighbor sets the tone for all that follows. Any technical solutions cannot help if you are not allowed in your neighbor’s house to explain them! If the interference is not caused by spurious emissions from your station, however, you should be a locator of solutions, not a provider of solutions.

Your neighbor will probably *not* understand all of the technical issues — at least not at first. Understand that, regardless of fault, an interference problem is annoying to your neighbor. Let your neighbor know that you want to help find a solution and that you want to begin by talking things over.

Talk about some of the more important technical issues, in nontechnical terms. Interference can be caused by unwanted signals from your transmitter. Assure your neighbor that you will check your station thoroughly and correct any problems. You should also discuss the possible susceptibility of consumer equipment. If you have a copy of the consumer pamphlet “What to Do If You Have an Electronic Interference

Problem,” give it to your neighbor.<sup>2</sup>

Here is a good analogy: If you tune your TV to channel 3, and see channel 8 instead, would you blame channel 8? No. You might check another set to see if it has the same problem, or call channel 8 to see if the station has a problem. If channel 8 was operating properly, you would likely decide that your TV set is broken. Now, if you tune your TV to channel 3, and see your local shortwave radio station (quite possibly Amateur Radio), don’t blame the shortwave station without some investigation. In fact, many televisions respond to strong signals outside the television bands. They may be working as designed, but require added filters and/or shields to work properly near a strong, local RF signal.

Your neighbor will probably feel much better if you explain that you will help *find* a solution, even if the interference is *not* your fault. This offer can change your image from neighborhood villain to hero, especially if the interference is not caused by your station. (This is often the case.)

## PREPARE YOURSELF

### Learn About EMI

In order to troubleshoot and cure EMI, you need to learn more than just the basics. This is especially important when dealing with your neighbor. If you visit your neighbor’s house and try a few dozen things that don’t work (or make things worse), your neighbor may lose confidence in your ability to help cure the problem. If that happens, you may be asked to leave.

### Local Help

If you are not an expert (and even experts can use moral support), you should find some local help. Fortunately, such help is often available from your Section Technical Coordinator (TC). The TC knows of any local RFI committees, and may have valuable contacts in the local utility companies. Even an expert can benefit from a TC’s help.

<sup>2</sup>The ARRL “EMI/RFI Package” contains additional information about EMI, a list of EMI-filter sources, EMI-resistant telephones, telephone-company contacts and a pamphlet that explains interference in nontechnical terms. It is available from the ARRL Technical Department Secretary. Send a 9×12-inch SASE with three units of First-class postage and a specific request for the “EMI/RFI Package.”

The easiest way to find your TC is through your ARRL Section Manager (SM). There is a list of ARRL Officers and SMs on page 8 of any recent *QST*. Contact your SM through the address or telephone number listed. He or she can quickly put you in contact with the best source of local help.

Even if you can’t secure the help of a local expert, a second ham can be a valuable asset. Often a second party can help defuse any hostility. It is also helpful to have someone to operate your station while you and your neighbor run through troubleshooting steps and try various cures.

## Prepare Your Home

The first step toward curing an interference problem is to make sure your own signal is clean. You must eliminate all interference in your own house to be sure you are not causing the interference! This is also a valuable troubleshooting tool: If you know your station is clean, you have cut the size of the problem in half! If the FCC ever gets involved, you can demonstrate that you are not interfering with your own equipment.

Apply EMI cures to your own consumer electronics equipment. When your neighbor sees your equipment working well, it demonstrates that filters work and cause no harm.

To clean up your station, clean up the mess! A rat’s nest of wires, unsoldered connections and so on in your station can contribute to EMI. To help build a better relationship, you may want to show your station to your neighbor. A clean station looks professional; it inspires confidence in your ability to solve the EMI problem.

Install a transmit filter (low-pass or band-pass) and a reasonable station ground. (If the FCC becomes involved, they will ask you about both items.) Show your neighbor that you have installed the necessary filter on your transmitter and explain that if there is still interference, it is necessary to try filters on the neighbor’s equipment, too.

Operating practices and station-design considerations can affect EMI. Don’t overdrive a transmitter or amplifier; that can increase its harmonic output. You can take steps to reduce the strength of your signal at the victim equipment. This might include reducing transmit power. Locate the antenna as far as possible from susceptible equipment or its wiring (ac line, telephone, cable TV). Antenna orientation

**Table 28.1**

**EMI Survival Kit**

**Literature:**

- *The ARRL Handbook*
- *Radio Frequency Interference — How to Find It and Fix It*
- "What To Do If You Have an Electronic Interference Problem" (the consumer pamphlet)
- The ARRL "EMI/RFI Package"
- The ARRL "EMI/RFI — Telephone" information package

**Filters:**

- (2) 300-Ω high-pass filter (different brands recommended)
- (2) 75-Ω high-pass filter (different brands recommended)
- (2) Commercially available common-mode chokes
- (12) Assorted ferrite cores: 43, 63 and 75 material, FT-140 and FT-240 size
- (3) Telephone RFI filters (different brands recommended)
- (2) Brute-force ac line filters
- (6) 0.01-μF ceramic capacitors
- (6) 0.001-μF ceramic capacitors
- (2) Speaker-lead filters

**Miscellaneous:**

- Hand tools, assorted screwdrivers, wire cutters, pliers
- Hookup wire
- Electrical tape
- Soldering iron and solder (use with caution!)
- Assorted lengths 75-Ω coaxial cable with connectors
- Spare F connectors, male
- F-connector female-female "barrel"
- Alligator clips
- Notebook and pencil
- Portable multimeter

may be important. For example, if your HF dipole at 30 ft is coupling into the neighbor's overhead cable-TV drop, that coupling could be reduced 20 dB by changing to a vertical antenna — even more by orienting the antenna so that the drop is off its end. Try different modes; CW or FM usually do not generate nearly as much telephone interference as AM or SSB, for example.

**Call Your Neighbor**

Now that you have learned more about EMI, located some local help (we'll assume it's the TC) and done all of your homework, make contact with your neighbor. First, arrange an appointment convenient for you, the TC and your neighbor. After you introduce the TC, allow him or

her to explain the issues to your neighbor. Your TC will be able to answer most questions, but be prepared to assist with support and additional information as required.

Invite the neighbor to visit your station. Show your neighbor some of the things you do with your radio equipment. Point out any test equipment you use to keep your station in good working order. Of course, you want to show the filters you have installed on your transmitter.

Next, have the TC operate your station on several different bands. Show your neighbor that your home electronics equipment is working properly while your station is in operation. Point out the filters you have installed to correct any susceptibility problems.

## EMC Fundamentals

Knowledge is one of the most valuable tools for solving EMI problems. A successful EMI cure usually requires familiarity with the relevant technology and troubleshooting procedures.

**SOURCE-PATH-VICTIM**

All cases of EMI involve a *source* of

electromagnetic energy, a device that responds to this electromagnetic energy (*victim*) and a transmission path that allows energy to flow from the source to the victim. Sources include radio transmitters, receiver local oscillators, computing devices, electrical noise, lightning and other natural sources.

### Warning: Performing Repairs

You are the best judge of a local situation, but the ARRL strongly recommends that you do not work on your neighbor's equipment. The minute you take the back off a TV or open up a telephone, you may become liable for problems. Internal modifications to your neighbor's equipment may cure the interference problem, but months later, when that 25-year-old clunker gives up the ghost, you may be held to blame. In many states, it is *illegal* for you to do any work on electronic equipment other than your own. — *Ed Hare, KA1CV, ARRL Laboratory Supervisor*

At this point, tell your neighbor that the next step is to try some of these cures on his or her equipment. This is a good time to emphasize that the problem is probably not your fault, but that you and the TC will try to help find a solution anyway.

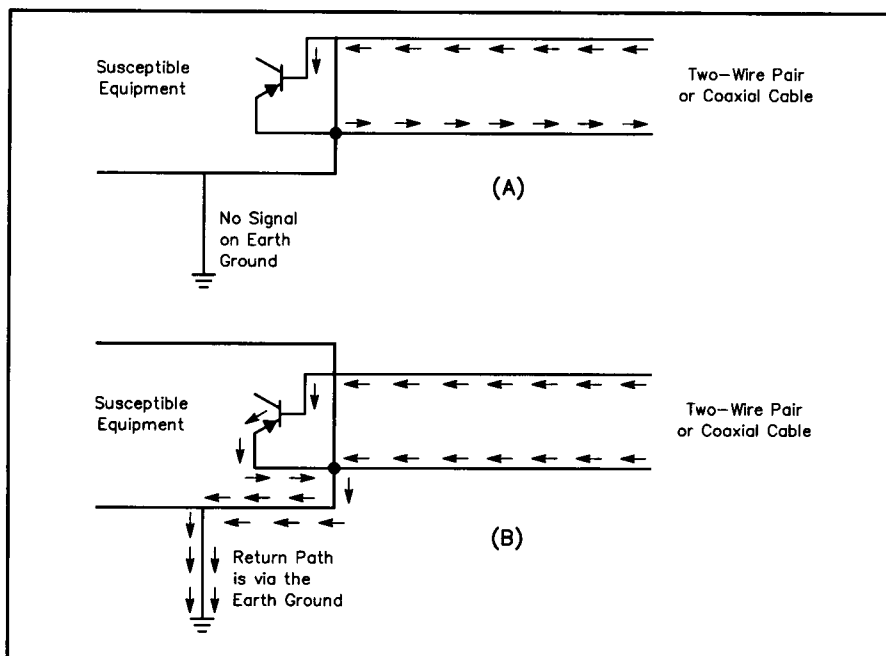

**Table 28.1** is a list of the things needed to troubleshoot and solve most EMI problems. Decide ahead of time which of these items are needed and take them with you.

### At Your Neighbor's Home

You and the TC should now visit the neighbor's home. Inspect the equipment installation and ask when the interference occurs, what equipment is involved and what frequencies or channels are affected. The answers are valuable clues. Next, either you or the TC should operate your station while the other observes the effects. Try all bands and modes that you use. Ask the neighbor to demonstrate the problem.

The tests may show that your station isn't involved at all. You may immediately recognize electrical noise or some kind of equipment malfunction. If so, explain your findings to the neighbor and suggest that he or she contact appropriate service personnel.

There are three ways that EMI can travel from the source to the victim: radiation, conduction and induction. Radiated EMI propagates by electromagnetic radiation from the source, through space to the victim. A conducted signal travels over wires connected to the source and the victim. Induction occurs when two circuits

**Fig 28.1 — A shows a differential-mode, while B shows a common-mode signal. The two kinds of signals are described in the text.**

are magnetically coupled. Most EMI occurs via conduction, or some combination of radiation and conduction. For example, a signal is radiated by the source and picked up by a conductor attached to the victim (or directly by the victim's circuitry) and is then conducted into the victim. EMI from induction is rare.

### DIFFERENTIAL VS COMMON-MODE

It is important to understand the differences between differential-mode and common-mode conducted signals (see Fig 28.1). Each of these conduction modes requires different EMI cures. Differential-mode cures, (the typical high-pass filter, for example) do not attenuate common-mode signals. On the other hand, a typical common-mode choke does not affect interference resulting from a differential-mode signal.

Differential-mode currents usually have two easily identified conductors. In a two-wire transmission line, for example, the signal leaves the generator on one line and returns on the other. When the two conductors are in close proximity, they form a transmission line and there is a 180° phase difference between their respective signals. It's relatively simple to build a filter that passes desired signals and shunts unwanted signals to the return line. Most *desired* signals, such as the TV signal inside a coaxial cable are differential-mode signals.

In a common-mode circuit, many wires of a multiwire system act as if they were a

single wire. The result can be a good antenna, either as a radiator or as a receptor of unwanted energy. The return path is usually earth ground. Since the source and return conductors are usually well separated, there is no reliable phase difference between the conductors and no convenient place to shunt unwanted signals. Toroid chokes are the answer to common-mode interference. (The following explanation applies to rod cores as well as toroids, but since rod cores may couple into nearby circuits, use them only as a last resort.)

Toroids work differently, but equally well, with coaxial cable and paired conductors. A common-mode signal on a coaxial cable is usually a signal that is present on the *outside* of the cable *shield*. When we wrap the cable around a ferrite-toroid core the choke appears as a reactance in series with the outside of the shield, but it has no effect on signals inside the cable because their field is (ideally) confined inside the shield. With paired conductors such as zip-cord, signals with opposite phase set up magnetic fluxes of opposite phase in the core. These "differential" fluxes cancel each other, and there is no net reactance for the differential signal. To common-mode signals, however, the choke appears as a reactance in series with the line.

Toroid chokes work less well with single-conductor leads. Because there is no return current to set up a canceling flux, the choke appears as a reactance in series with *both* the desired and undesired signals.

## SOURCES OF EMI

The basic causes of EMI can be grouped into several categories:

- Fundamental overload effects
- External noise
- Spurious emissions from a transmitter
- Intermodulation distortion or other external spurious signals

As an EMI troubleshooter, you must determine which of these are involved in your interference problem. Once you do, it is easy to select the necessary cure.

### Fundamental Overload

Most cases of interference are caused by fundamental overload. The world is filled with RF signals. Properly designed equipment should be able to select the desired signal, while rejecting all others. Unfortunately, because of design deficiencies such as inadequate shields or filters, some equipment is unable to reject strong out-of-band signals.

A strong fundamental signal can enter equipment in several different ways. Most commonly, it is conducted into the equipment by wires connected to it. Possible conductors include antennas and feed lines, interconnecting cables, power lines and ground wires. TV antennas and feed lines, telephone or speaker wiring and ac power leads are the most common points of entry.

The effect of an interfering signal is directly related to its strength. The strength of a radiated signal diminishes with the square of the distance from the source: When the distance from the source doubles, the strength of the electromagnetic field decreases to one-fourth of its strength at the original distance from the source. This characteristic can often be used to help solve EMI cases. You can often make a significant improvement by moving the victim equipment and the antenna farther away from each other.

### External Noise

Most cases of interference reported to the FCC involve some sort of external noise source. The most common of these noise sources are electrical. External "noise" can also come from transmitters or from unlicensed RF sources such as computers, video games, electronic mice repellers and the like.

Electrical noise is fairly easy to identify by looking at the picture of a susceptible TV or listening on an HF receiver. A photo of electrical noise on a TV screen is shown in the TVI section of this chapter. On a receiver, it usually sounds like a buzz, sometimes changing in intensity as the arc or spark sputters a bit. If you determine

the problem to be caused by external noise, it must be cured at the source. Refer to the Electrical Noise section of this chapter and the ARRL RFI book.

## Spurious Emissions

All transmitters generate some (hopefully few) RF signals that are outside their allocated frequency bands. These out-of-band signals are called spurious emissions, or *spurs*. Spurious emissions can be discrete signals or wideband noise. Harmonics, the most common spurious emissions, are signals at exact multiples of the operating (or *fundamental*) frequency. Other discrete spurious signals are usually caused by the superheterodyne mixing process used in most modern transmitters. Fig 28.2 shows the spectral output of a transmitter, including harmonics and mixing products.

Transmitters may also produce broadband noise and/or “parasitic” oscillations. (Parasitic oscillations are discussed in the **Amplifiers** chapter.) If these unwanted signals cause interference to another radio service, FCC regulations require the owner to correct the problem.

## Troubleshooting EMI

Most EMI cases are complex. They involve a source, a path and a victim. Each of these main components has a number of variables: Is the problem caused by harmonics, fundamental overload, conducted emissions, radiated emissions or a combination of all of these factors? Should it be fixed with a low-pass filter, high-pass filter, common-mode chokes or ac-line filter? How about shielding, isolation transformers, a different ground or antenna configuration?

By the time you finish with these questions, the possibilities could number in the millions. You probably will not see your exact problem and cure listed in this book or any other. You must diagnose the problem!

Troubleshooting an EMI problem is a three-step process, and all three steps are equally important:

- Identify the problem

## Cures

**At Your Station** — Make sure that your own station and consumer equipment are clean. This cuts the size of the problem in half! Once this is done, you won’t need to diagnose or troubleshoot your station later. Also, any cures successful at your house may work at your neighbor’s as well. If you do have problems in your own house,

**Fig 28.2 — The spectral output of a typical amateur transmitter. The fundamental is at 7 MHz. There are visible harmonics at 14, 21 and 28 MHz. Unlabeled lines are nonharmonic spurious emissions. This transmitter complies with the stringent FCC spectral-purity regulations regarding amateur transmitters with less than 5 W of RF output.**

- Diagnose the problem
- Cure the problem.

## IDENTIFY THE PROBLEM

**Is It Really EMI?** — Before trying to solve a suspected case of EMI, verify that the symptoms actually result from external causes. A variety of equipment malfunctions or external noise can look like interference. “Your” EMI problem might be caused by another ham or a radio transmitter of another radio service, such as a local CB or police transmitter.

**Is It Your Station?** — If it appears that your station is involved, operate your station on each band, mode and power level that you use. Note all conditions that produce interference. If no transmissions produce the problem, your station *may* not be the cause. (Although some contributing factor may have been missing in the test.) Have your neighbor keep notes of when and how the interference appears: what time of day, what station, what other appliances were in use, what was the weather? You should do the same whenever you operate. If you can readily reproduce the problem with your station, you

can start to troubleshoot the problem.

## DIAGNOSE THE PROBLEM

**Look Around** — Aside from the brain, eyes are a troubleshooter’s best tool. Look around. Installation defects contribute to many EMI problems. Look for loose connections, shield breaks in a cable-TV installation or corroded contacts in a telephone installation. Fix these first.

Problems that occur only on harmonics of the fundamental signal usually indicate the transmitter. Harmonics can also be generated in nearby semiconductors, such as an unpowered VHF receiver left connected to an antenna, or a corroded connection in a tower guy wire. Harmonics can also be generated in the front-end components of the TV or radio experiencing interference.

Is the wiring connected to the victim equipment resonant on one or more amateur bands? If so, a common-mode choke placed at the middle of the wiring may be an easy cure.

These are only a few of the questions you might need to ask. Any information you gain about the systems involved will help find the EMI cause and cure.

refer first to the Transmitter section of this chapter, or continue through the troubleshooting steps and specific cures and take care of your own problem first.

**Simplify the Problem** — Don’t tackle a complex system — such as a telephone system in which there are two lines running to 14 rooms — all at once. You could spend

the rest of your life running in circles and never find the true cause of the problem.

There’s a better way. In our hypothetical telephone system, first locate the telephone jack closest to the telephone service entrance. Disconnect the lines to more remote jacks and connect one EMI-resistant telephone at the remaining jack.

Fig 28.3 — An example of a low-pass filter response curve.

Fig 28.5 — An example of a high-pass filter response curve.

If the interference remains, try cures until the problem is solved, then start adding lines and equipment back one at a time, fixing the problems as you go along. If you are lucky, you will solve all of the problems in one pass. If not, at least you can point to one piece of equipment as the source of the problem.

**Multiple Causes** — Many EMI problems have multiple causes. These are usually the ones that give new EMI trouble-shooters the most trouble. If, for example, a TVI problem is caused by harmonics from the transmitter, an arc in the transmitting antenna, an overloaded TV preamp, differential-mode fundamental overload generating harmonics in the TV tuner, induced and conducted RF in the ac-power system and a common-mode signal picked up on the shield of the TV's coaxial feed line, you would never find a cure by trying only one at a time!

In this case, the solution requires that you apply all of the cures at the same time. When troubleshooting, if you try a cure, leave it in place. When you finally try a cure that really works, start removing the "temporary" attempts one at a time. If the interference returns, you know that there were multiple causes.

## OVERVIEW OF TECHNIQUES

### Shields

Shields are used to set boundaries for

Fig 28.4 — A low-pass filter for amateur transmitting use. Complete construction information appears in the Transmitters chapter of the ARRL RFI book.

Fig 28.6 — A differential-mode high-pass filter for 75-Ω coax. It rejects HF signals picked up by a TV antenna or that leak into a cable-TV system. It is ineffective against common-mode signals. All capacitors are high-stability, low-loss, NP0 ceramic discs. Values are in pF. The inductors are all #24 enameled wire on T-44-0 toroid cores. L4 and L6 are each 12 turns (0.157  $\mu$ H). L5 is 11 turns (0.135  $\mu$ H).

radiated energy. Thin conductive films, copper braid and sheet metal are the most common shield materials. Maximum shield effectiveness usually requires solid sheet metal that completely encloses the source or susceptible circuitry or equipment. Small discontinuities, such as holes or seams, decrease shield effectiveness.

### Filters

A major means of separating signals relies on their frequency differences. Filters offer little opposition to certain frequencies while blocking others. Filters vary in attenuation characteristics, frequency characteristics and power-handling capabilities. The names given to various filters are based on their uses.

**Low-pass filters** pass frequencies below some cutoff frequency, while attenuating frequencies above that cutoff frequency. A typical low-pass filter curve is shown in Fig 28.3. A schematic is shown in Fig 28.4. These filters are difficult to construct properly so you should buy one. Many retail Amateur Radio stores that advertise in *QST* stock low-pass filters.

**High-pass filters** pass frequencies above some cutoff frequency while attenuating frequencies below that cutoff frequency. A typical high-pass filter curve is shown in Fig 28.5. Fig 28.6 shows a schematic of a typical high-pass filter. Again, it is best to buy one of the commercially available filters.

Fig 28.7 — A "brute-force" ac-line filter.

**Bypass capacitors** can be used to cure EMI problems. A bypass capacitor is usually placed between a signal or power lead and circuit ground. It provides a low-impedance path to ground for RF signals. Bypass capacitors for HF signals are usually 0.01  $\mu$ F, while VHF bypass capacitors are usually 0.001  $\mu$ F.

**AC-line filters**, sometimes called "brute-force" filters, are used to filter RF energy from power lines. A schematic is shown in Fig 28.7. Use ac-rated components as specified. We *strongly* recommend UL-listed, commercially made ac-line filters; the ac-power lines are no place for home-brew experimentation.

### Common-Mode Chokes

Common-mode chokes may be the best-kept secret in Amateur Radio. The differential-mode filters described earlier are

## Warning: Surplus Toroidal Cores

Don't use an unknown core or an old TV yoke core to make a common-mode choke. Such cores may not be suitable for the frequency you want to remove. If you try one of these "unknowns" and it *doesn't* work, you may incorrectly conclude that a common-mode choke won't help. Perhaps the correct material would have done the job.

Ferrite beads are also used for EMI control, both as common-mode chokes and low-pass filters. It takes quite a few beads to be effective at the lower end of the HF range, though. It is usually better to form a common-mode choke by wrapping about 10 to 20 turns of wire or coaxial cable around an FT-140 (1.4-inch OD) or FT-240 (2.4-inch OD) core of the correct material. Mix 43 is a good material for most of the HF and VHF ranges. — *Ed Hare, KA1CV, ARRL Laboratory Supervisor*

Fig 28.8 — Several styles of common-mode chokes.

not effective against common-mode signals. To eliminate common-mode signals properly, you need common-mode chokes. They may help nearly any interference problem, from cable TV to telephones to audio interference caused by RF picked up on speaker leads.

Common-mode chokes usually have ferrite core materials. These materials are well suited to attenuate common-mode currents. Several kinds of common-mode chokes are shown in Fig 28.8.

The optimum size and ferrite material are determined by the application and frequency. For example, an ac cord with a

plug attached cannot be easily wrapped on a small ferrite core. The characteristics of ferrite materials vary with frequency, as shown by the graph in Fig 28.9.

## Grounds

An electrical ground is not a huge sink that somehow swallows noise and unwanted signals. Grounding is the establishment of an electrically conductive path between two electrical systems. Ground is a *circuit* concept, whether that circuit is small, like a radio receiver, or large, like the propagation path between a transmitter and a cable TV installation via a common-mode signal. Think of ground as a universal reference. The ideal reference point (a zero-impedance, zero-potential body) can only be approximated.

Many amateur stations have several grounds: a safety ground that is part of the ac-wiring system, another at the antenna for lightning protection, another at the station for EMI control and so on. These grounds can interact in ways that are difficult to predict.

The EMI or station ground is used for:

1. cable-shield and equipment grounding,
2. as an EMI filter reference point and
3. as a circuit reference point common to the various circuits used as station components.

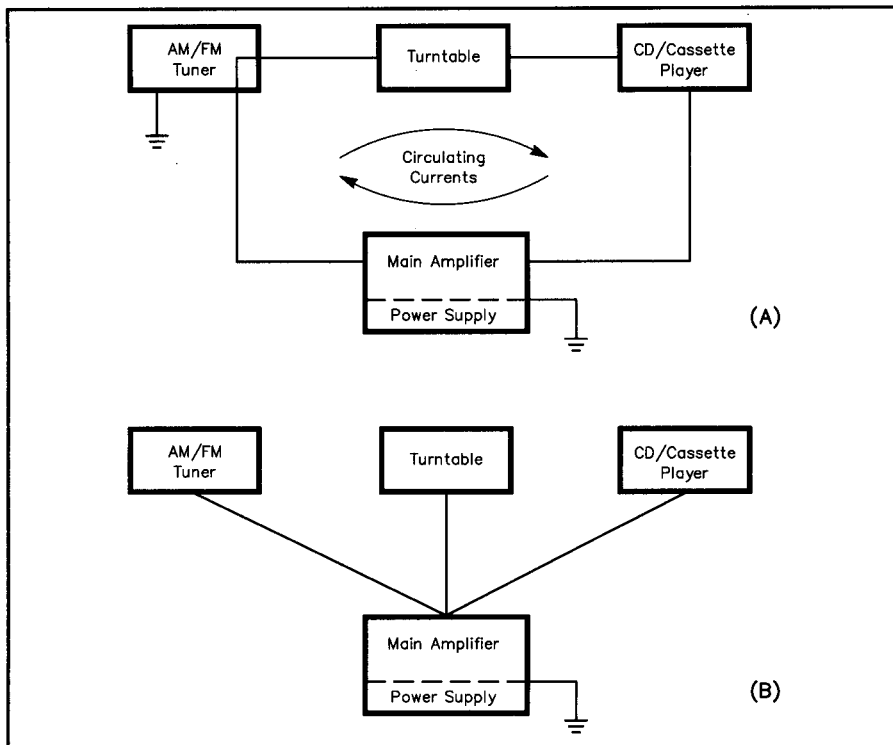

Fig 28.10 — A shows a stereo system grounded as an undesirable "ground loop." B is the proper way to ground a multiple-component system.

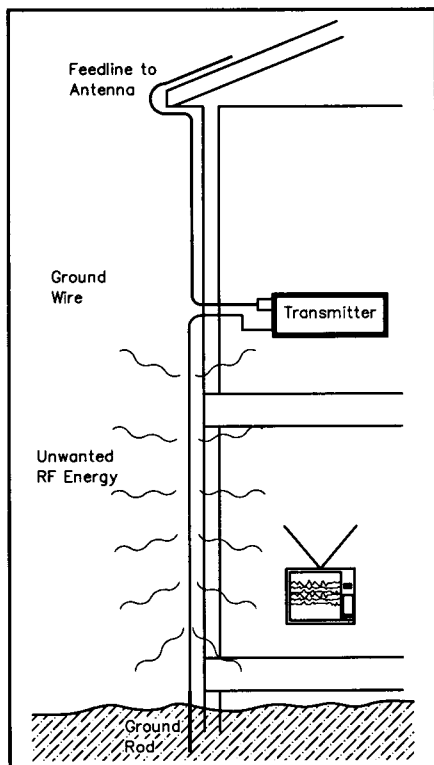

Fig 28.9 — Impedance vs frequency plots for "101" size ferrite beads.

**Fig 28.11** — When a transmitter is located on an upper floor, the ground lead may act as an antenna for VHF/UHF energy. Such stations may be better off without a normal ground.

### Ground Loops

All of these station grounds can form a large ground loop. This loop can act as a large loop antenna, with increased susceptibility to lightning or EMI problems. **Fig 28.10** shows a ground loop and a proper single-point ground system.

### When is Ground not a Ground?

In many stations, it is impossible to get a good RF connection to earth ground. Most practical installations require several feet of wire between the station ground connection and an outside ground rod. Many troublesome harmonics are in the VHF range. At VHF, a ground wire length can be several wavelengths long — a very effective long-wire antenna! Any VHF signals that are put on that ground wire-antenna will be radiated. This is usually not the intended result of grounding.

Take a look at the station shown in **Fig 28.11**. In this case, the ground wire could very easily contribute to an interference problem in the downstairs TV set.

While a station ground may cure some transmitter EMI problems — either by putting the transmitter chassis at a low-impedance reference point or by rearrang-

ing the problem so the “hot spots” are farther away from susceptible equipment — it is not the cure-all that some literature has suggested. A ground is easy to try, however, and it may reduce stray fundamental or harmonic currents on your antenna lead; it is worth a try.

### SPECIFIC CURES

Now that you have learned some EMI fundamentals, you can work on technical solutions. A systematic approach will identify the problem and suggest a cure. Armed with your EMI knowledge, a kit of filters and tools, your local TC and a determination to solve the problem, it is time to diagnose the problem.

Most EMI problems can be solved by the application of standard cures. If you try these cures and they work, you may not need to troubleshoot the problem at all. Perhaps if you can install a low-pass filter on your transmitter or a common-mode choke on a TV, the problem will be solved.

Here are some specific cures for different interference problems. You should also get a copy of the ARRL RFI book. It's comprehensive and picks up where this chapter leaves off. Here are several standard cures.

### Transmitters

We start with transmitters not because most interference comes from transmitters, but because your station transmitter is under your direct control. Many of the troubleshooting steps in other parts of this chapter assume that your transmitter is “clean” (free of unwanted RF output).

**Controlling Spurious Emissions** — Start by looking for patterns in the interference. If the interference is only on frequencies that are multiples of your operating frequency, you clearly have interference from harmonics. (Although these harmonics may *not* come from your station!)

If HF-transmitter spurs are interfering with a VHF service, a low-pass filter on the transmitter will usually cure the problem. Install it after the amplifier (if used) and *before* the antenna tuner. (A second filter between the transmitter and amplifier may occasionally help as well.) Install a low-pass filter as your first step in any interference problem that involves another radio service.

Interference from nonharmonic spurious emissions is extremely rare in commercially built radios. Any such problem indicates a malfunction that should be repaired.

### Television Interference (TVI)

For a TV signal to look good, it must

have about a 45 to 50 dB signal-to-noise ratio. This requires a good signal at the TV antenna-input connector. This brings up an important point: to have a good signal, you must be in a good signal area. The FCC does not protect fringe-area reception.

TVI, or interference to any radio service, can be caused by one of several things:

- Spurious signals within the TV channel coming from your transmitter or station.
- The TV set may be overloaded by your transmitter's fundamental signal.
- Signals within the TV channel from some source other than your station, such as electrical noise, an overloaded mast-mounted TV preamplifier or a transmitter in another service.
- The TV set might be defective or misadjusted, making it look like there is an interference problem.

All of these potential problems are made more severe because the TV set is hooked up to *two* antenna systems: (1) the incoming antenna and its feed line and (2) the ac power lines. These two “long-wire” antennas can couple *a lot* of fundamental or harmonic energy into the TV set! Your job, as a TVI sleuth, is to figure out which one (or more) of these possibilities is actually at fault and locate the appropriate cures.

### Fundamental Overload

A television set can be overloaded by a strong, local RF signal. This happens because the manufacturer did not install the necessary filters and shields to protect the TV set from other signals present on the air. These design deficiencies can sometimes be corrected externally.

Start by determining if the interference is affecting the video, the sound or both. If it is present only on the sound, it is probably a case of audio rectification. (See the Stereos section of this chapter.) If it is present on the video, or both, it could be getting into the video circuitry or affecting either the tuner or IF circuitry.

The first line of defense for an antenna-connected TV is a high-pass filter. Install a high-pass filter directly on the back of the TV set. You may also have a problem with common-mode interference. The second line of defense is a common-mode choke on the antenna feed line — try this first in a cable-television installation. These two filters can probably cure most cases of TVI!

**Fig 28.12** shows a “bulletproof” installation. If this doesn't cure the problem, the TV circuitry is picking up your signal directly. In that case, don't try to fix it yourself — it is a problem for the TV manufacturer.

**Fig 28.12 — This sort of installation should cure any kind of conducted TVI. It will not cure direct-pickup or spurious-emission problems.**

**VHF Transmitters** — A VHF transmitter can interfere with over-the-air TV reception. Most TV tuners are not very selective and a strong VHF signal can overload the tuner easily. In this case, a VHF notch or stop-band filter at the TV can help by reducing the VHF fundamental signal that gets to the TV tuner. Star Circuits is one company that sells tunable notch filters.<sup>3</sup>

The Electronic Industries Association (EIA) maintains a list of contact people at each equipment manufacturer. Contact them directly for assistance in locating help. (Their address is in the **References** chapter Address List.)

#### **Spurious Emissions**

Start by analyzing which TV channels are affected. The TV Channel Chart in the

**References** chapter shows the relationship of the ham allocations and their harmonics to over-the-air and cable channels. Each channel is 6-MHz wide. If the interference is only on channels that are multiples of your operating frequency, you clearly have interference from harmonics.

(It is not certain that these harmonics are coming from your station, however.)

You are responsible for spurious signals produced by your station. If your station is generating any interfering spurious signals, the problem must be cured there. So, if the problem occurs only when you transmit, go back and check your station. Refer to the section on Transmitters. You must first find out if the transmitter has any spurs.

If your transmitter and station check "clean," then you must look elsewhere. The most likely cause is TV susceptibility — fundamental overload. This is usually manifest by interference to all channels, or at least all VHF channels. If the problem is fundamental overload, see that section earlier in this chapter. If not, read on.

#### **Electrical Noise**

Electrical noise is fairly easy to identify by looking at the picture or listening on an HF receiver. Electrical noise on a TV screen is shown in **Fig 28.13**. On a receiver, it usually sounds like a buzz, sometimes changing in intensity as the arc or spark sputters a bit. If you have a problem with electrical noise, go to the Electrical Noise section.

#### **Cable TV**

Cable TV has been a blessing and a curse for Amateur Radio TVI problems. On the plus side, the cable delivers a strong, consistent signal to the TV receiver. It is also (in theory) a shielded system, so an external signal can't get in and cause trouble. On the minus side, the cable forms a large, long-wire antenna that can pick up lots of external signals on its shield (in the common mode). Many TVs and VCRs and even some cable set-top converters are easily overloaded by such common-mode signals.

Leakage into a cable-TV system is called ingress. Leakage out is called egress. If the

**PATTERN A**

**PATTERN B**

**Fig 28.13 — Two examples of TVs experiencing electrical noise.**

<sup>3</sup>Star Circuits Model: 23H tunes 6 m, Model: 1822 tunes 2 m and Model: 46FM tunes the FM broadcast band. Their address is in the **References** chapter Address List.

**Fig 28.14** — Several turns of coax on a ferrite core eliminate HF and VHF signals from the outside of a coaxial cable.

cable isn't leaking, there should be no external signals getting inside the cable. So, an in-line filter such as a high-pass filter is not usually necessary. For a cable-connected TV, the first line of defense is a common-mode choke. Only in rare cases is a high-pass filter necessary. It is important to remember this, because if your neighbor has several TVs connected to cable and you suggest the wrong filter (at \$15 each), you may have a personal diplomacy problem of a whole new dimension. **Fig 28.14** shows a common-mode choke.

**Fig 28.12** shows a bulletproof installation for cable TV. (The high-pass filter is usually not needed.) If all of the cures shown have been tried, the interference probably results from direct pickup inside the TV. In this case, contact the TV manufacturer through the EIA.

Interference to cable-TV installations from VHF transmitters is a special case. Cable TV uses frequencies allocated to over-the-air services, such as Amateur Radio. When the cable shielding is less than perfect, interference can result.

The TV Channel Chart in the **References** chapter shows which cable channels coincide with ham bands. If, for example, you have interference to cable channel 18 from amateur 2-m operation, suspect cable ingress. Contact the cable company; it may be their responsibility to locate and correct the problem. The cable company is not responsible, however, for leakage occurring in customer-owned, cable-ready equipment that is tuned to the same frequency as the over-the-air signal. If there is interference to a cable-TV installation, the cable company should be able to demonstrate interference-free reception when using a cable-company supplied set-top converter.

#### **TV Preamplifiers**

Some television owners use a preampli-

fier — sometimes when it's not needed. Preamplifiers are only needed in weak-signal areas, and they often cause more trouble than they prevent. They are subject to the same overload problems as TVs, and their location on the antenna mast usually makes it difficult to install the appropriate cures. You may need to install a high-pass or notch filter at the *input* of the preamplifier, as well as a common-mode choke on the input, output and power-supply wiring (if separate) to effect a complete cure.

#### **VCRs**

A VCR usually contains a television tuner, or has a TV channel output, so it is subject to all of the interference problems of a TV receiver. It is also hooked up to an antenna or cable system and the ac-line wiring. The video baseband signal extends from 30 Hz to 3.5 MHz, with color information centered around 3.5 MHz and the FM sound subcarrier at 4.5 MHz. The entire video baseband is frequency modulated onto the tape at frequencies up to 10 MHz. It is no wonder that some VCRs are quite susceptible to EMI.

Many cases of VCR EMI can be cured. Start by proving that the VCR is the susceptible device. Temporarily disconnect

the VCR from the television. If there is no interference to the TV, then the VCR is the most likely culprit.

You need to find out how the interfering signal is getting into the VCR. Temporarily disconnect the antenna or cable feed line from the VCR. If the interference goes away, then the antenna line is involved. In this case, you can probably fix the problem with a common-mode choke or high-pass filter.

**Fig 28.12** shows a bulletproof VCR installation. If you have tried all of the cures shown and still have a problem, the VCR is probably subject to direct pickup. In this case, contact the manufacturer through the EIA.

#### **Nonradio Devices**

Interference to nonradio devices is not the fault of the transmitter. (A portion of the *FCC Interference Handbook*, 1990 Edition, is shown in **Fig 28.15**.<sup>4</sup>) In essence, the FCC views nonradio devices that pick up nearby radio signals as im-

<sup>4</sup>*FCC Interference Handbook* — 1990 Edition is available from FCC Field Offices or by sending a 9x12-inch SASE with four units of First-Class postage to the ARRL Regulatory Information Branch.

## **PART II**

# **INTERFERENCE TO OTHER EQUIPMENT**

## **CHAPTER 6**

### **TELEPHONES, ELECTRONIC ORGANS, AM/FM RADIOS, STEREO AND HI-FI EQUIPMENT**

Telephones, stereos, computers, electronic organs and home intercom devices can receive interference from nearby radio transmitters. When this happens, the device improperly functions as a radio receiver. Proper shielding or filtering can eliminate such interference. The device receiving interference should be modified in your home while it is being affected by interference. This will enable the service technician to determine where the interfering signal is entering your device.

The device's response will vary according to the interference source. If, for example, your equipment is picking up the signal of a nearby two-way radio transmitter, you likely will hear the radio operator's voice. Electrical interference can cause sizzling, popping or humming sounds.

**Fig 28.15** — Part of page 18 from *FCC Interference Handbook* (1990 edition) explains the facts and places responsibility for interference to nonradio equipment.

properly functioning; contact the manufacturer and return the equipment. The FCC does not require that nonradio devices include EMI protection and they don't offer legal protection to users of these devices that are susceptible to interference.

### Telephones

Telephones have probably become the number one interference problem of Amateur Radio. However, most cases of telephone interference can be cured by correcting any installation defects and installing telephone EMI filters where needed.

Telephones can improperly function as radio receivers. There are devices inside many telephones that act like diodes. When such a telephone is connected to the telephone wiring (a large antenna), an AM radio receiver can be formed. When a nearby transmitter goes on the air, these telephones can be affected.

Troubleshooting techniques were discussed earlier in the chapter. The suggestion to simplify the problem applies especially to telephone interference. Disconnect all telephones except one, right at the service entrance if possible, and start troubleshooting the problem there.

If any one device, or bad connection in the phone system, detects RF and puts the detected signal back onto the phone line as audio, that audio cannot be removed with filters. Once the RF has been detected and turned into audio, it cannot be filtered out because the interference is at the same frequency as the desired audio signal. To effect a cure, you must locate the detection point and correct the problem there.

The telephone company lightning arrestor may be defective. Defective arrestors can act like diodes, rectifying any nearby RF energy. Telephone-line amplifiers or other electronic equipment may also be at fault. Leave the telephone company equipment to the experts, however. There are important safety issues that are the sole responsibility of the telephone company.

Inspect the installation. Years of exposure in damp basements, walls or crawl spaces may have caused deterioration. Be suspicious of anything that is corroded or discolored. In many cases, homeowners have installed their own telephone wiring, often using substandard wiring. If you find sections of telephone wiring made from nonstandard cable, replace it with standard twisted-pair wire. Radio Shack, among others, sells several kinds of telephone wire.

Next, evaluate each of the telephone instruments. If you find a susceptible telephone, install a telephone EMI filter on that telephone. Several *QST* advertisers

sell small, attractive telephone EMI filters.

If you determine that you have interference only when you operate on one particular ham band, the telephone wiring is probably resonant on that band. If possible, install a few strategically placed in-line telephone EMI filters to break up the resonance.

**Telephone Accessories** — Answering machines, fax machines and some alarm systems are also prone to interference problems. All of the troubleshooting techniques and cures that apply to telephones also apply to these telephone devices. In addition, many of these devices connect to the ac mains. Try a common-mode choke and/or ac-line filter on the power cord (which may be an ac cordset, a small transformer or power supply).

**Cordless Telephones** — A cordless telephone is an unlicensed *radio* device that is manufactured and used under Part 15 of the FCC regulations. The FCC does not intend Part 15 devices to be protected from interference. These devices usually have receivers with very wide front-end filters, which make them very susceptible to interference. A label on the telephone or a paragraph in the owner's manual should explain that the telephone must not cause interference to other services and must tolerate any interference caused to it.

It's worthwhile to try a telephone filter on the base unit and properly filter its ac line cord. (You might get lucky!) The best source of help is the manufacturer, but they may point out that the Part 15 device is not protected from interference. These kinds of problems are difficult to fix after the fact. The necessary engineering should be done when the device is designed.

### Other Audio Devices

Other audio devices, such as stereos, in-

tercoms and public-address systems can also pick up and detect strong nearby transmitters. The FCC considers these nonradio devices and does not protect them from licensed radio transmitters that may interfere with their operation. See Fig 28.15 for the FCC's point of view.

Use the standard troubleshooting techniques discussed earlier in this chapter to isolate problems. In a multicomponent stereo system (as in Fig 28.16), for example, you must determine what combination of components is involved with the problem. First, disconnect all auxiliary components to determine if there is a problem with the main receiver/amplifier. (Long speaker/interconnect cables are prime suspects.)

**Stereos** — If the problem remains with the main amplifier isolated, determine if the interference level is affected by the volume control. If so, the interference is getting into the circuit *before* the volume control, usually through accessory wiring. If the volume control has no effect on the level of the interfering sound, the interference is getting in *after* the control, usually through speaker wires.

**Speaker wires** are often resonant on the HF bands. In addition, they are often connected directly to the output transistors, where RF can be detected. Most amplifier designs use a negative feedback loop to improve fidelity. This loop can conduct the detected RF signal back to the high-gain stages of the amplifier. The combination of all of these factors makes the speaker leads the usual indirect cause of interference to audio amplifiers.

There is a simple test that will help determine if the interfering signal is being coupled into the amplifier by the speaker leads. Temporarily disconnect the speaker leads from the amplifier, and plug in a test set of headphones with short leads. If there is no interference with the headphones,

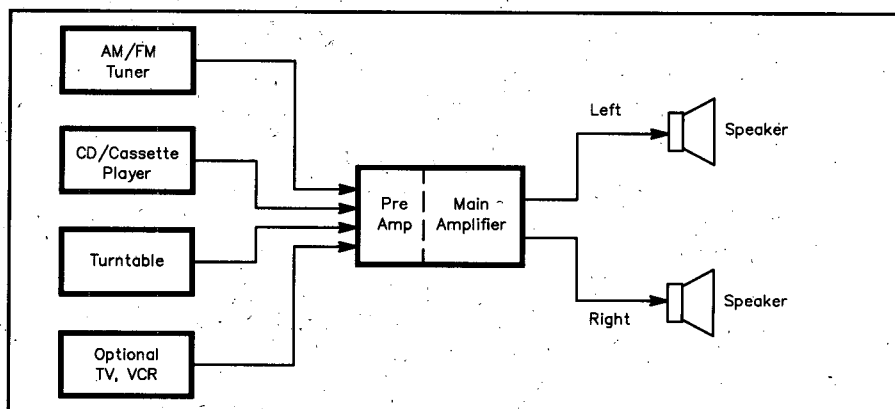

Fig 28.16 — A typical modern stereo system.

### Warning: Bypassing Speaker Leads

Older amateur literature might tell you to put a 0.01- $\mu$ F capacitor across the speaker terminals to cure speaker-lead interference. *Don't do this!* Some modern solid-state amplifiers can break into a destructive, full-power, sometimes ultrasonic oscillation if they are connected to a highly capacitive load. If you do this to your neighbor's amplifier, you will have a whole new kind of personal diplomacy problem! — Ed Hare, KA1CV, ARRL Laboratory Supervisor

Fig 28.17 — This is how to make a speaker-lead common-mode choke. Be sure to use the correct ferrite material.

Fig 28.18 — An LC filter for speaker leads.

Fig 28.19 — A filter for use at the input of audio equipment. The components should be installed inside of the chassis at the connector by a qualified technician.

filtering the speaker leads will cure the problem.

The best way to eliminate RF signals from speaker leads is with common-mode chokes. Fig 28.17 shows how to wrap speaker wires around an FT-140-43 ferrite core to cure speaker-lead EMI. Use the correct core material for the job. See the information about common-mode chokes earlier in this chapter.

Another way to cure speaker-lead interference is with an LC filter as shown in Fig 28.18. Sources for similar filters are listed in the ARRL Technical Information Service (TIS) "EMI/RFI Package."

Interconnect cables can couple interfering signals into an amplifier or accessories. The easiest cure here is also a common-mode choke. However, it may also be necessary to add a differential-mode filter to the input of the amplifier or accessory. Fig 28.19 shows a home-brew version of such a filter.

**Intercoms and Public-Address Systems** — All of these problems also apply to intercoms, public-address (PA) systems and similar devices. These systems usually have long speaker leads or interconnect cables that can pick up a lot of RF energy from a nearby transmitter. The cures discussed above do apply to these systems, but you may also need to contact the manufacturer to see if they have any additional, specific information.

### Computers and Other Unlicensed RF Sources

Computers and microprocessors can be sources, or victims, of interference. These devices contain oscillators that can, and do, radiate RF energy. In addition, the internal functions of a computer generate different frequencies, based on the various data rates as software is executed. All of these signals are digital in nature — with fast rise and fall times that are rich in harmonics.

Don't just think "computer" when thinking of computer systems. Many household appliances contain microprocessors: digital clocks, video games, calculators and more.

Computing devices are covered under Part 15 of the FCC regulations as unintentional emitters. The FCC has set up absolute radiation limits for these devices. FCC regulations state that the operator or owner of Part 15 devices must take whatever steps are necessary to reduce or eliminate any interference they cause to a licensed radio service. This means that if your neighbor's video game interferes with your radio, the neighbor is responsible for correcting the problem. (Of course, your neighbor may appreciate your

help in locating a solution!)

The FCC has set up two levels of type acceptance for computing devices. Class A is for computers used in a commercial environment. FCC Class B requirements are more stringent — for computers used in residential environments. If you buy a computer or peripheral, be sure that it is Class B certified or it will probably generate interference to your amateur station or home-electronics equipment.

If you find that your computer system is interfering with your radio (not uncommon in this digital-radio age), start by simplifying the problem. Temporarily switch off as many peripherals as possible and disconnect their cables from the back of the computer. If possible, use just the computer, keyboard and monitor. This test may indicate one or more peripherals as the source of the interference.

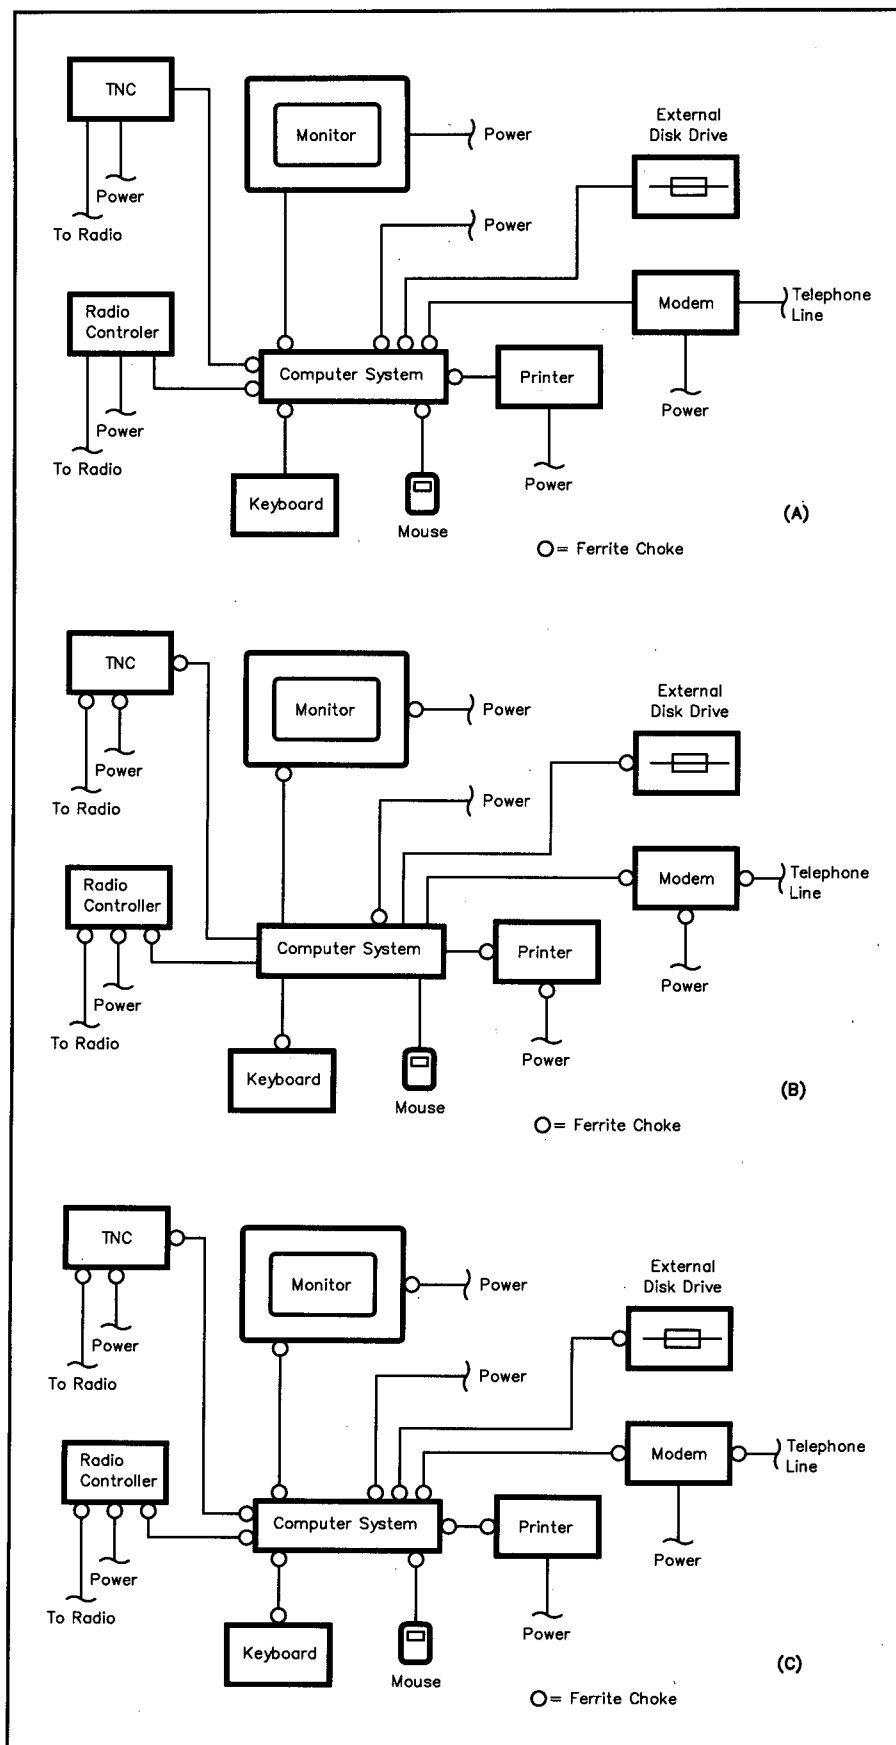

When seeking cures, first ensure that all interconnection cables are shielded. Replace any unshielded cables with well shielded ones; this often significantly reduces RF noise from computer systems. The second line of defense is the common-mode choke, made from a ferrite toroid. The toroids should be installed as close to the computer and/or peripheral device as practical. Fig 28.20 shows the location of common-mode chokes in a complete computer system where both the computer and peripherals are noisy.

In some cases, a switching power supply may be a source of interference. A common-mode choke and/or ac-line filter may cure this problem. In extreme cases of computer interference you may need to improve the shielding of the computer. Refer to the ARRL RFI book for more information about how to do this. Don't forget that some peripherals (such as modems) are connected to the phone line, so you may need to treat them like telephones.

### Automobiles

As automobiles have become more technologically sophisticated, questions about the compatibility of automobiles and amateur transmitters have increased in number and scope. The use of microprocessors in autos makes them computer systems on wheels, subject to all of the same problems as any other computer. Installation of ham equipment can cause problems, ranging from nuisances like a dome light coming on every time you transmit to serious ones such as damage to the vehicle electronic control module (ECM).

Only qualified service personnel should work on automotive EMC problems. Many critical safety systems on modern

**Fig 28.20 — Where to locate ferrites in a computer system. At A, the computer is noisy, but the peripherals are quiet. At B, the computer is quiet, but external devices are noisy. At C, both the computer and externals are noisy.**

cars should not be handled by amateurs. Even professionals can meet with mixed results. The ARRL (TIS) contacted each of the automobile manufacturers and asked about their EMC policies, service bulletins and best contacts to resolve EMI problems. About 20% of the companies never answered, and answers from the rest ranged from good to poor. One company even said that the answers to those questions were "proprietary."

Some of the companies *do* have reasonable EMC policies, but these policies often fall apart at the dealer level. The ARRL has reports of problems with nearly every auto manufacturer. Check with your dealer before you install a transceiver in a car. The dealer can direct you to any service bulletins or information that is applicable to your model. If you are not satisfied with the dealer's response, contact the regional or factory customer service representatives.

The ARRL TIS maintains a file on each manufacturer, as well as a list of contact people that can help. The TIS can also supply a reprint of the General Motors installation guidelines.<sup>5</sup> For additional information about automotive EMC, refer to the Automobiles chapter in the ARRL RFI book.

### Electrical Noise

Many electrical appliances and power lines can generate electrical noise. On a receiver, electrical noise usually sounds like a rough buzz, heard across a wide frequency range. The buzz will either have a strong 60- or 120-Hz component, or its pitch will vary with the speed of a motor that generates the noise. The appearance of electrical noise on a television set is shown in the TVI section of this chapter. This kind of noise can come from power lines, electrical motors or switches, to name just a few. Here is one quick diagnostic trick — if electrical noise seems to come and go with the weather, the source is probably outside, usually on the power lines. If electrical noise varies with the time of day, it is usually related to what people are doing, so look to your own, or your neighbors', house and lifestyle. The ARRL RFI book describes techniques for locating RFI sources.

Filters usually cure electrical noise. At its source, the noise can usually be filtered with a differential-mode filter. A differen-

<sup>5</sup>The ARRL "EMI/RFI — GM Installations Guidelines" is a reprint of the General Motors booklet. Send a 9x12-inch SASE with three units of First-Class postage and a specific request for the "EMI/RFI GM Installation Guidelines" to TIS at ARRL HQ.

tial-mode filter can be as simple as a 0.01- $\mu$ F ac-rated capacitor, such as Panasonic part ECQ-U2A103MN, or it can be a pi-section filter like that shown in Fig 28.7.

For removing signals that arrive via power lines, a common-mode choke is usually the best defense. Wrap about 10 turns of the ac-power cord around an FT-240-43 ferrite core; do this as close as possible to the device you are trying to protect.

Electrical noise can also indicate a dangerous electrical condition that needs to be corrected. The ARRL has recorded sev-

eral cases where defective or arcing doorbell transformers caused widespread neighborhood electrical interference. This subject is well covered in the *Interference Handbook* or the ARRL RFI book.<sup>6</sup>

**Power Lines** — Electrical noise can also come from power lines. Diagnosis and repair of power-line problems *must* be left to professionals. It is even dangerous to

<sup>6</sup>*Interference Handbook*, ISBN 0-8230-8709-3, ARRL Order no. 6015, available from ARRL Publication Sales Department or your local Amateur Radio equipment dealer.

tap poles with a hammer as a diagnostic tool; broken insulators can fall and possibly strike people or passing cars. If you have a problem with power-line noise, contact the utility company for help. Most electric utility companies have qualified, knowledgeable personnel to correct EMI problems.

### ***In Conclusion***

Remember that EMI problems can be cured. With the proper technical knowledge and interpersonal skills, you can deal effectively with the people and hardware that make up any EMI problem.

# Regulations

## Glossary

**Amateur Service**—A radio communication service for the purpose of self-training, intercommunication and technical investigations carried out by amateurs, that is, duly authorized persons interested in radio technique solely with a personal aim and without pecuniary interest.

**Auxiliary station**—An amateur station transmitting communications point-to-point within a system of cooperating amateur stations.

**Bandwidth**—The width of a transmitted frequency band outside of which the mean power of the transmitted signal is attenuated at least 26 dB below the mean power of the transmitted signal within the band.

**Beacon**—An amateur station transmitting communications for the purposes of observation of propagation and reception or other related experimental activities.

**Broadcasting**—Transmissions intended for reception by the general public, either direct or relayed.

**Carrier power**—The average power supplied to the antenna transmission line by a transmitter during one RF cycle taken under the condition of no modulation.

**Control operator**—An amateur operator designated by the licensee of a station to be responsible for the transmissions from that station to assure compliance with the FCC Rules.

**Control point**—The location at which the control operator function is performed.

**Covenants**—Private contractual agreements between two parties. PRB-1 does not apply to such agreements.

**CW**—International Morse code telegraphy emissions having designators with A, C, H, J or R as the first symbol; 1 as the second symbol; A or B as the third symbol; and emissions J2A and J2B. See the sidebar, "Classification of Emissions."

**Data**—Telemetry, telecommand and computer communications emissions having designators with A, C, D, F, G, H, J or R as the first symbol; 1 as the second symbol; D as the third symbol; and emission J2D. Only a digital code of a type specifically authorized in this Part may be transmitted. See the sidebar, "Classification of Emissions."

**External RF power amplifier**—A device capable of increasing power output when used in conjunction with, but not an integral part of, a transmitter.

**External RF power amplifier kit**—A number of electronic parts, which, when assembled, is an external RF power amplifier, even if additional parts are required to complete assembly.

**FCC**—Federal Communications Commission.

**Frequency coordinator**—An entity, recognized in a local or regional area by amateur operators whose stations are eligible to be auxiliary or repeater stations, that recommends transmit/receive channels and associated operating and technical parameters for such stations in order to avoid or minimize potential interference.

**Harmful interference**—Interference which endangers the functioning of a radionavigation service or of other safety services or seriously degrades, obstructs or repeatedly interrupts a

radiocommunication service operating in accordance with the Radio Regulations.

**Image**—Facsimile and television emissions having designators with A, C, D, F, G, H, J or R as the first symbol; 1, 2 or 3 as the second symbol; C or F as the third symbol; and emissions having B as the first symbol; 7, 8 or 9 as the second symbol; W as the third symbol. See the sidebar, "Classification of Emissions."

**Information bulletin**—A message directed only to amateur operators consisting solely of subject matter of direct interest to the amateur service.

**International Morse code**—A dot-dash code as defined in International Telegraph and Telephone Consultative Committee (CCITT) Recommendation F.1 (1984), Division B, I. Morse Code.

**ITU**—International Telecommunication Union.

**Key clicks**—Undesired switching transients beyond the necessary bandwidth of a Morse code transmission caused by improperly shaped modulation envelopes.

**Mean power**—The average power supplied to an antenna transmission line during an interval of time sufficiently long compared with the lowest frequency encountered in the modulation taken under normal operating conditions.

**Necessary bandwidth**—The width of the transmitted frequency band which is just sufficient to ensure the transmission of information at the rate and with the quality required under specified conditions.

**Occupied bandwidth**—The width of the transmitted frequency band such that, below the lower and above the upper frequency limits, the mean powers emitted are each equal to 0.5% (−23dB) of the total mean power of a given emission.

**Out-of-band emission** (splatter)—An emission on a frequency immediately outside the necessary bandwidth caused by overmodulation on peaks (excluding spurious emissions).

**PEP** (peak envelope power)—The average power supplied to the antenna transmission line by a transmitter during one RF cycle at the crest of the modulation envelope taken under normal operating conditions.

**Phone**—Emissions carrying speech or other sound information having designators with A, C, D, F, G, H, J or R as the first symbol; 1, 2 or 3 as the second symbol; E as the third symbol. Also speech emissions having B as the first symbol; 7, 8 or 9 as the second symbol; E as the third symbol. See the sidebar, "Classification of Emissions."

**Power**—Power is expressed in three ways: (1) Peak envelope power (PEP); (2) Mean power; and (3) Carrier power.

**PRB-1**—The limited federal government preemption of local zoning ordinances which states that local zoning authorities must be reasonable and that regulation must represent the minimum practicable to accomplish its legitimate purpose.

**Pulse**—Emissions having designators with K, L, M, P, Q, V or W as the first symbol; 0, 1, 2, 3, 7, 8, 9 or X as the second symbol; A, B, C, D, E, F, N, W or X as the third symbol. See the sidebar, "Classification of Emissions."

**RF**—Radio frequency.

**Radio Regulations**—The latest ITU *Radio Regulations* to which the United States is a party.

**RACES** (Radio Amateur Civil Emergency Service)—A radio service that uses amateur stations for civil defense communications during periods of local, regional or national civil emergencies.

**Remote control**—The use of a control operator who indirectly manipulates the operating adjustments in the station through a control link to achieve compliance with the FCC Rules.

**Repeater**—An amateur station that simultaneously retransmits the signals of other stations.

**RTTY**—Narrow-band direct-printing telegraphy emissions having designators with A, C, D, F, G, H, J or R as the first symbol; 1 as the second symbol; B as the third symbol; and emission J2B. See the sidebar, "Classification of Emissions."

**Space station**—An amateur station located more than 50 km above the Earth's surface.

**Splatter**—See *Out-of-band emission*.

**Spurious emission**—An emission, on frequencies outside the necessary bandwidth of a transmission, the level of

which may be reduced without affecting the information being transmitted.

**SS**—Spread-spectrum emissions using bandwidth-expansion modulation emissions having designators with A, C, D, F, G, H, J or R as the first symbol; X as the second symbol; X as the third symbol. Only an SS emission of a type specifically authorized by Part 97 may be transmitted. See the sidebar, "Classification of Emissions."

**Telecommand**—A one-way transmission to initiate, modify, or terminate functions of a device at a distance.

**Telecommand station**—An amateur station that transmits communications to initiate, modify, or terminate functions of a space station.

**Telemetry**—A one-way transmission of measurements at a distance from the measuring instrument.

**Test**—Emissions containing no information having the designators with N as the third symbol. Test does not include pulse emissions with no information or modulation unless pulse emissions are also authorized in the frequency band. See the sidebar, "Classification of Emissions."

**Type acceptance**—An equipment authorization granted by the FCC. It is used to ensure that equipment will function properly in the service for which it has been accepted. Amateur equipment does not require type acceptance although HF power amplifiers and amplifier kits do.

**I**nternational and national radio regulations govern the operational and technical standards of all radio stations. The International Telecommunication Union (ITU) governs telecommunications on the international level and broadly defines radio services through the international Radio Regulations. In the United States, its trust territories and possessions, the agency responsible for non-governmental and nonmilitary stations is the Federal Communications Commission (FCC). Title 47 of the *US Code of Federal Regulations* governs telecommunications. Different rule Parts of Title 47 govern the various radio services in the US. The Amateur Radio Service is governed by Part 97. Some other Parts are described in the sidebar "Other FCC Rule 'Parts'."

Experimentation has been the backbone of Amateur Radio for almost a century and the amateur rules provide a framework within which amateurs have wide latitude to experiment in accordance with the basis

### Other FCC Rule "Parts"

Part 97 is just a small piece of the overall regulatory picture. The *US Code of Federal Regulations*, Title 47, consists of telecommunications rules numbered as Parts 0 through 200. These Parts contain specific rules for the many telecommunications services the FCC administers. Individuals may purchase a specific rule Part for a particular service from the Superintendent of Documents, US Government Printing Office (see the Address List in the **References** chapter). Here is a list of FCC Parts amateurs may find of interest:

#### Part

- 0 Commission organization
- 1 Practice and procedure
- 2 Frequency allocation and radio treaty matters; general rules and regulations, and type acceptance procedures
- 15 Low-power radio-frequency transmitting devices
- 17 Construction, marking and lighting of antenna structures
- 18 Industrial, scientific and medical equipment
- 73 Radio broadcast services
- 76 Cable Television Service
- 90 Private Land Mobile Radio Service
- 95 Personal radio services, including CB and GMRS
- 97 Amateur Radio Service

## Classification of Emissions

### §2.201 Emission, modulation and transmission characteristics.

The following system of designating emission, modulation and transmission characteristics shall be employed.

(a) Emissions are designated according to their classification and their necessary bandwidth.

(b) A minimum of three symbols are used to describe the basic characteristics of radio waves. Emissions are classified and symbolized according to the following characteristics:

- (1) First symbol—type of modulation of the main carrier;
- (2) Second symbol—nature of signal(s) modulating the main carrier;
- (3) Third symbol—type of information to be transmitted.

Note: A fourth and fifth symbol are provided for additional information and are shown in Appendix 6, Part A of the ITU Radio Regulations. Use of the fourth and fifth symbol is optional. Therefore, the symbols may be used as described in Appendix 6, but are not required by the Commission.

(c) First symbol—types of modulation of the main carrier:

- (1) Emission of an unmodulated carrier ..... N
- (2) Emission in which the main carrier is amplitude-modulated (including cases where subcarriers are angle-modulated):
  - Double sideband ..... A
  - Single sideband, full carrier ..... H
  - Single sideband, reduced or variable level carrier ..... R
  - Single sideband, suppressed carrier ..... J
  - Independent sidebands ..... B
  - Vestigial sideband ..... C
- (3) Emission in which the main carrier is angle-modulated:
  - Frequency modulation ..... F
  - Phase modulation ..... G

Note: Whenever frequency modulation (F) is indicated, \* phase modulation (G) is also acceptable.

- (4) Emission in which the main carrier is amplitude- and angle-modulated either simultaneously or in a pre-established sequence ..... D
- (5) Emission of pulses<sup>1</sup>
  - Sequence of unmodulated pulses ..... P
  - A sequence of pulses:
    - Modulated in amplitude ..... K
    - Modulated in width/duration ..... L
    - Modulated in position/phase ..... M
    - In which the carrier is angle-modulated during the period of the pulse ..... Q

—Which is a combination of the foregoing or is produced by other means ..... V

- (6) Cases not covered above, in which an emission consists of the main carrier modulated, either simultaneously or in a pre-established sequence in a combination of two or more of the following modes: amplitude, angle, pulse ..... W
- (7) Cases not otherwise covered ..... X

(d) Second Symbol—nature of signal(s) modulating the main carrier:

- (1) No modulating signal ..... 0
- (2) A single channel containing quantized or digital information without the use of a modulating subcarrier, excluding time-division multiplex ..... 1
- (3) A single channel containing quantized or digital information with the use of a modulating subcarrier, time-division multiplex ..... 2
- (4) A single channel containing analog information ..... 3
- (5) Two or more channels containing quantized or digital information ..... 7
- (6) Two or more channels containing analog information ..... 8
- (7) Composite system with one or more channels containing quantized or digital information, together with one or more channels containing analog information ..... 9
- (8) Cases not otherwise covered ..... X

(e) Third Symbol—type of information to be transmitted:<sup>2</sup>

- (1) No information transmitted ..... N
- (2) Telegraphy, for aural reception ..... A
- (3) Telegraphy, for automatic reception ..... B
- (4) Facsimile ..... C
- (5) Data transmission, telemetry, telecommand ..... D
- (6) Telephony (including sound broadcasting) ..... E
- (7) Television (video) ..... F
- (8) Combination of the above ..... W
- (9) Cases not otherwise covered ..... X

(f) Type B emission: As an exception to the above principles, damped waves are symbolized in the Commission's rules and regulations as type B emission. The use of type B emissions is forbidden.

(g) Whenever the full designation of an emission is necessary, the symbol for that emission, as given above, shall be preceded by the necessary bandwidth of the emission as indicated in § 2.202(b)(1).

<sup>1</sup>Emissions where the main carrier is directly modulated by a signal which has been coded into quantized form (e.g., pulse code modulation) should be designated under (2) or (3).

<sup>2</sup>In this context, the word "information" does not include information of a constant, unvarying nature such as is provided by standard frequency emissions, continuous wave and pulse radars, etc.

and purpose of the service. The rules should be viewed as vehicles to promote healthy activity and growth, not as constraints that lead to stagnation. A brief overview of Amateur Radio regulations follows with special emphasis on technical standards.

## BASIS AND PURPOSE OF THE AMATEUR RADIO SERVICE

There's much more in the regulatory scheme than Part 97. The basis for the FCC regulations is found in treaties, international agreements and statutes that provide for the allocation of frequencies and

place conditions on how the frequencies are to be used. For example, Article 32 of the international *Radio Regulations* limits the types of international communications amateur stations may transmit and mandates that the technical qualifications of amateur operators be verified.

It's the FCC's responsibility to see that amateurs are able to operate their stations in a manner consistent with the basis and purpose of the amateur rules. The FCC must also ensure that amateurs have the knowledge and ability to operate powerful and potentially dangerous equipment safely without causing interference to other radio services. The sidebar "The FCC's Role" discusses the Commission in a bit more detail. A review of each of the five basic purposes of the Amateur Radio Service, as they appear in Part 97, follows:

**Recognition and enhancement of the**

**value of the amateur service to the public as a voluntary noncommercial communication service, particularly with respect to providing emergency communications** [97.1(a)].

Probably the best known aspect of Amateur Radio to the general public is its ability to provide emergency communications. One of the most important aspects of the service is its noncommercial nature. Amateurs are prohibited from receiving any form of payment for operating their stations.

**Continuation and extension of the amateur's proven ability to contribute to the advancement of the radio art** [97.1(b)].

For nearly a century, hams have carried on a tradition of learning by doing, and since the beginning have remained at the forefront of technology. Through experimenting and building, hams have pioneered advances, such as techniques for single-sideband transmissions, and are currently engaged in the development of new digital schemes which continue to improve the efficiency of such communications. Hams' practical experience has led to technical refinements and cost reductions beneficial to the commercial radio industry.

**Encouragement and improvement of the Amateur Radio Service through rules which provide for advancing skills in both the communication and technical phases of the art** [97.1(c)]

Amateurs have always been experimenters and that's what sets the Amateur Service apart from other services. The cost to the government for licensing and en-

forcement is minimal when compared to the benefit the public receives. Hams have contributed greatly to the development of computer communications techniques. The FCC and industry have also credited the amateur community with the development of Low-Earth-Orbit (LEO) satellite technology. The same can be said for a number of digital modes that have arrived on the scene in the 1990s, such as PacTOR and CLOVER.

**Expansion of the existing reservoir within the Amateur Radio Service of trained operators, technicians and electronic experts** [97.1(d)]

Amateurs learn by doing. While all amateurs may not be able to troubleshoot and repair a transceiver, all amateurs have some degree of technical competence.

**Continuation and extension of the amateur's unique ability to enhance international goodwill** [97.1(e)].

Amateur Radio is one of the few truly international hobbies. It is up to amateurs to maintain high standards and to represent the US as its ambassadors, because, in a sense, all US amateurs serve that function.

## A QUICK JOURNEY THROUGH PART 97

The Amateur Radio Service rules, Part 97, are organized in six major subparts: General Provisions, Station Operation Standards, Special Operations, Technical Standards, Providing Emergency Communications and Qualifying Examination Systems. A brief discussion of the highlights of each subpart follows:

### General Provisions

Subpart A covers the basics that apply to all facets of Amateur Radio. The "Basis and Purpose" of Amateur Radio, discussed above, is found at the beginning of Part 97 [97.1]. Definitions of key terms used throughout Part 97 form the foundation of Part 97 [97.3].

This subpart contains a useful incorporation of FCC policy on limited preemption of state and local restrictions on amateur antenna installations called PRB-1. The federal government has a strong interest in amateurs being allowed "reasonable" antennas. The policy has encouraged open cooperation and dialogue between amateurs and communities that seek to regulate amateur towers and antennas. [97.15(e)]. See the sidebars "Federal Restrictions on the Installation of Amateur Antennas" and "Local Zoning Ordinances, Covenants and Deed Restrictions" for rules concerning the installation of antennas, and ways of dealing with local zoning ordinances.

The remainder of the subpart is devoted

### The FCC's Role

The Federal Communications Commission (FCC) is the US government agency charged by Congress with regulating communications involving radio, television, wire, cable and satellites. This includes Amateur Radio. The objective of the FCC is to provide for orderly development and operation of telecommunications services.

The FCC functions like no other Federal agency. It was created by Congress and it reports directly to Congress. The FCC allocates bands of frequencies to nongovernment communications services and assigns operator privileges. (The National Telecommunications and Information Administration allocates government frequencies.)

### Federal Restrictions on the Installation of Amateur Antennas

The following Federal restrictions apply to amateur antennas:

- Amateurs must take certain actions before placing an amateur station on land of environmental importance or on land significant in American history, architecture, or culture [97.13(a)].
- Amateurs must protect FCC monitoring stations from harmful interference if an amateur is operating within one mile of such a facility [97.13(b)].
- Amateurs must have the FCC's approval before installing a tower over 200 ft high [97.15(a)].
- Amateurs located near airports must meet additional limitations [97.15(b) and (c)]. Details appear in *The FCC Rule Book*.
- Amateurs may install an antenna up to 20 ft above the ground or other natural features or on top of any man-made structure except antenna towers. Such antennas are exempt from the rules described in 97.15(a) and (b). [97.15(c)].
- Amateurs must notify the Director of the National Radio Astronomy Observatory if a repeater or beacon antenna is planned for the National Radio Quiet Zone, a small area in Maryland, Virginia and West Virginia [97.205(f)] and [97.203(e)].

ham or group has any special claim to any frequency [97.101(b)]. The station licensee is always responsible for the proper operation of an amateur station, except where the control operator is someone other than the station licensee, in which case both share responsibility equally [97.103(a)].

The requirements for control operators and station control are also addressed in Subpart B. Each station must have a control point [97.109(a)]. A control operator must always be at the control point, except in a few cases where the transmitter is controlled automatically [97.109(b), (c), (d) and (e)]. The purpose of the Amateur Radio Service is to communicate with other amateurs [97.111]. Certain one-way transmissions are allowed. Amateurs can send a one-way transmission to:

- make adjustments to equipment for test purposes
- call CQ
- remotely control devices
- communicate information in emergencies
- send code practice and information bulletins of interest to amateurs [97.111(b)]

Broadcasting to the public is strictly prohibited [97.113(b)]. The section on prohibited transmissions states that amateurs cannot: be paid for operating a station, make transmissions on behalf of an employer, transmit music (unless otherwise allowed in the rules), transmit obscenity, use amateur stations for news-gathering purposes or transmit false signals and ciphers. The FCC has relaxed the previously restrictive business rules to encourage public service and personal communications [97.113].

Station identification is addressed in

this subpart. The purpose of station identification is to make the source of its transmissions known to those receiving them, including FCC monitors. The rules cover identification requirements for the various operating modes. Section 97.119 details the station-identification requirements. Amateurs must transmit their call sign at the end of the communication and every 10 minutes during communications. CW and phone may be used to identify an amateur station. RTTY and data (using a specified digital code) may be used when all or part of the communications are transmitted using such an emission. Images (Amateur Television, for example) may be used to identify when all or part of the transmission is in that mode. A final section addresses restricted operation and sets forth the conditions that must exist in an interference case involving a neighbor's TV or radio before the Commission can impose "quiet hours"—hours of the day when a particular amateur may not operate an amateur transmitter [97.121(a)]. Imposition of quiet hours by the FCC is rare, however.

### Special Operations

Subpart C, "Special Operations," addresses specialized activities of Amateur Radio including the various types of stations an amateur may operate. This subpart gives specific guidelines concerning repeaters, beacons, space stations, Earth stations, message forwarding systems, and telecommand (remote control) stations. These rules are of particular interest to the technically minded amateur. An amateur may send ancillary functions (user functions) of a repeater on the input of the repeater—to turn on and off an autopatch, for example. However, the primary control links used to turn the repeater on and

off, for example, may be transmitted only above 222.150 MHz since such one-way transmissions are auxiliary transmissions. Every repeater trustee/licensee and user should understand the rules for repeaters and auxiliary links. An important regulatory approach to solving interference problems between repeaters is addressed in that section: Repeater station licensees are equally responsible for resolving an interference problem, unless one of the repeaters has been approved for operation by the recognized repeater coordinator for the area and the other has not. In that case, the owner of the uncoordinated repeater has primary responsibility to resolve the problem [97.205(c)]. The control operator of a repeater that inadvertently retransmits communications in violation of the rules is not held accountable [97.205(g)]. The originator and first forwarding station of a message transmitted through a message forwarding system are held accountable for any violations of Part 97. Other forwarding stations are not held accountable [97.219].

### Technical Standards

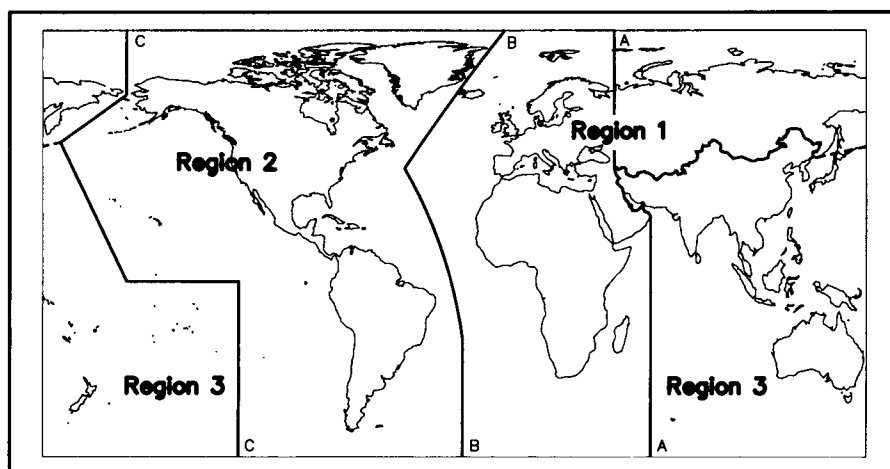

The word *standard* means consistency and order—and this is what the technical standards in Subpart D are all about. The FCC outlines the specific frequency bands available to US amateurs [97.301] as well as the sharing agreements [97.303]. (The **References** chapter of this book includes a table of frequencies allocated to the Amateur Radio Service.) The Commission made these standards a basic framework so all types of amateur operation may peacefully coexist with other radio occupants in the spectrum neighborhood. Emission standards for RTTY, data and spread spectrum are discussed, as are standards for the type acceptance of RF power amplifiers. FCC type acceptance is not needed for most amateur equipment. This gives amateurs the freedom to experiment without being bound by specific equipment standards.

### Providing Emergency Communications

Subpart E, "Providing Emergency Communications," addresses disaster communications, stations in distress, communications for the safety of life and protection of property and the Radio Amateur Civil Emergency Service (RACES)

### Qualifying Examination Systems

The final subpart of the rules, Subpart F, deals with the examination system and covers exam requirements and elements and standards. In 1983, the Commission delegated much of the exam administration program to amateurs themselves. The

**Fig 29.2—Frequency allocations for Amateur Radio and other radio services can differ, depending on location. There are three administrative ITU Regions, each with its own allocations.**

rules provide for checks and balances on volunteer examiners (VEs), who administer exams at the local and regional levels. These checks and balances protect against fraud and provide integrity for the exam process.

## REGULATION, THE ITU AND FREQUENCY SHARING

The International Telecommunication Union (ITU), an agency of the United Nations, plays the vital role of dividing the spectrum for reallocation by the telecommunications authorities of individual countries. For convenience in organizing frequency allocations for the various services, the ITU has divided the world into three Regions: 1, 2 and 3. See Fig 29.2. North and South America and the adjoining waters comprise Region 2.

Frequency allocations for Amateur Radio and other services can differ among ITU Regions. Today, there are numerous radio services vying for pieces of the spectrum, all with legitimate purposes. To accommodate them all, the international and domestic regulatory agencies may allocate the same frequency bands to more than one service. While some of our allocations are *exclusive*, we share others on the basis of priority. In some cases, the Amateur Radio Service is *primary*. In other cases, amateurs are *secondary*. Stations in a secondary service must not cause harmful interference to, and are not protected from interference caused by stations in the primary service.

The FCC specifies amateur frequencies and what, if any, restrictions apply. Since the detailed list of frequencies and the sharing requirements is far too long to be included in this short chapter, they can be found in Subpart D of Part 97. *The FCC Rule Book* and *The ARRL Operating Manual* give details of the sharing requirements of each band.

Guidelines based upon the actual sharing requirements of amateur frequencies outlined in Section 97.303 follow:

- A station in a secondary service must not cause interference to and must accept interference from stations in the primary service.
- Stations in one ITU Region shall not cause harmful interference to services in another Region.
- Many other services share frequencies with amateurs on and above the 70 cm band, and amateurs must be mindful of these services.
- Amateurs near large military bases should check Section 97.303 carefully, since additional restrictions may apply.

## Voluntary Band Plans

Another aspect of frequency sharing is

voluntary band plans. Although the FCC Rules set aside portions of some bands for specific modes, there's still a need to further divide amateur bands among user groups by "gentlemen's agreements." These agreements usually emerge by consensus of the band occupants, and are sanctioned by a national body like ARRL. These agreements allow many modes of operation to be used by amateurs in a given band. For example, amateurs avoid the domestic "DX windows" set aside on some bands, so that stations can hear and work weak-signal DX stations. Detailed band plans for the amateur HF bands can be found in the **References** chapter of this book. The complete band plans can be found in the following ARRL books: *The FCC Rule Book*, *The Repeater Directory* and *The Operating Manual*.

## Emission Standards and Bandwidth

Like most of Part 97, the technical standards exist to promote operating techniques that make efficient use of the spectrum and minimize interference. The standards in Part 97 identify problems that must be solved. Section 97.307 spells out the standards FCC expects amateur signals to meet. It states, in part: "No amateur station transmission shall occupy more bandwidth than necessary for the information rate and emission type being transmitted, in accordance with good amateur practice" [97.307(a)]. Simply stated, don't transmit a wide signal when a narrow one will do. Specific bandwidth limits are given for RTTY and data emissions. Specific bandwidth limits are not given for other modes of operation, but amateurs must still observe good engineering and operator practice:

The rules state: "Emissions resulting from modulation must be confined to the band or segment available to the control operator" [97.307(b)]. Every modulated signal produces sidebands. Amateurs must not operate so close to the band edge that the sidebands extend out of the subband, even if the frequency readout says that the carrier is inside the band. Further: "Emissions outside the necessary bandwidth must not cause splatter or key-click interference to operations on adjacent frequencies" [97.307(b)]. The rules simply codify good operating practice. Key clicks or over-processed voice signals shouldn't cause interference up and down the band.

## Spurious emissions

Spurious emissions include harmonic emissions, parasitic emissions, intermodulation products and frequency conversion products, but do not include splatter [97.307(c)]. Definitions for *necessary bandwidth* and *out-of-band emission* ap-

pear in the **Glossary** at the beginning of this chapter. Also see Fig 29.3.

## Emission standards

The FCC is very specific concerning spurious emission standards [97.307(d)]. If an amateur transmitter or RF power amplifier was built after April 14, 1977, or first marketed after December 31, 1977, and transmits on frequencies below 30 MHz the mean power of any spurious emissions must:

- never be more than 50 mW;
- be at least 30 dB below the mean power of the fundamental emission, if the mean power output is less than 5 W; and
- be at least 40 dB below the mean power of the fundamental emission if the mean power output is 5 W or more.

The following requirements apply between 30 and 225 MHz [97.307(e)]:

- In transmitters with 25 W or less mean output power, spurs must be at least 40 dB below the mean power of the fundamental emission and never greater than 25  $\mu$ W (microwatt), but need not be reduced further than 10  $\mu$ W. This means that the spurs from a 25-W transmitter must be at least 60 dB down to meet the 25-W restriction.
- In transmitters with more than 25 W mean output power, spurious emissions must be at least 60 dB below the mean power of the fundamental emission.

## Transmitter Power Standards

Amateurs shall not use more power than necessary to carry out the desired communication [97.313(a)]. Don't use 700 W when 10 m is wide open, for example. No station may use more than 1.5 kW peak envelope power [97.313(b)] and no station may use more than 200 W in the 30-m band. Novices and Technicians are limited to 200 W in their HF segments [97.313(c)]. Amateurs may use no more than 50 W in the 70-cm band near certain military installations [97.313(f) and (g)].

The FCC has chosen and published the following standards of measurement: (1) Read an in-line peak-reading RF wattmeter that is properly matched; and (2) calculate the power using the peak RF voltage as indicated by an oscilloscope or other peak-reading device. Multiply the peak RF voltage by 0.707, square the result and divide by the load resistance. The SWR must be 1:1.

## External RF Power Amplifiers: Type Acceptance and Standards

In 1978, the FCC banned the manufacture and marketing of any external RF power amplifier or amplifier kit capable

of operation on any frequency below 144 MHz, unless the FCC has issued a grant of type acceptance for that model amplifier. The FCC also banned the manufacture and marketing of HF amplifiers that were capable of operation on 10 m to stem the flow of amplifiers being distributed for illegal use in and around frequencies used by CB operators.

Amateurs may still use amplifiers capable of operation on 10 m. While the rules may make it difficult to buy a new amplifier capable of operation on 10 m, the FCC allows amateurs to modify an amplifier to restore or include 10-m capability. An amateur may modify no more than one unit of the same model amplifier in any year without a grant of type acceptance [97.315(a)].

Of course, amateurs are permitted to build amplifiers, convert equipment from any other radio service for this use or to buy used amplifiers. Nonamateurs are specifically prohibited from building or modifying amplifiers capable of operation below 144 MHz without FCC type acceptance [97.315(a)]. All external amplifiers and amplifier kits capable of operation below 144 MHz must be type accepted by the FCC in order to be marketed [97.315(b)]. A number of amplifiers, manufactured prior to the April 28, 1978, cutoff were issued a waiver of the new regulations [97.315(b)(2)]. Amateurs may buy or sell an amplifier that has either been type accepted, granted a waiver or modified so that the grant is no longer valid. There are restrictions that would be valid

regardless of whether the amplifier was capable of operation below 144 MHz. Some amplifiers marketed before April 28, 1978, are covered under the waiver if they are the same model that was granted a waiver [97.315(b)(2)]. An individual amateur may sell his amplifier regardless of grants or waivers, provided that he sells it only to another amateur operator [97.315(b)(4)]. Amateurs may also sell a used amplifier to a bona fide amateur equipment dealer [97.315(b)(5)]. The dealer could sell those amplifiers only to other hams [97.315(b)(5)].

In some cases, the FCC will deny type acceptance. Some features that may cause a denial are (1) any accessible wiring which, when altered, would permit operation in a manner contrary to FCC rules; (2) circuit boards or similar circuitry to facilitate the addition of components to change the amplifier's operation characteristics in a manner contrary to FCC rules; (3) for operation or modification of the amplifier in a manner contrary to FCC rules; (4) any internal or external controls or adjustments to facilitate operation of the amplifier in a manner contrary to FCC rules; (5) any internal RF sensing circuitry or any external switch, the purpose of which is to place the amplifier in the transmit mode; (6) the incorporation of more gain than is necessary to operate in the amateur service.

## CONCLUSION

A common thread in Amateur Radio's history has been a dynamic regulatory environment that has nurtured technological growth and diversity. This thread continues to sew together the elements of Amateur Radio today and prepare it for tomorrow's challenges.

**Fig 29.3—Some of the keying sidebands are outside the necessary bandwidth. These are out-of-band emissions, but they are not considered spurious emissions. On the other hand, these sidebands must not interfere with other stations [97.307(b)]. The harmonics and parasitics shown in this figure are spurious emissions, and they must be reduced to the levels specified in Part 97. The FCC states that all spurious emissions must be reduced "to the greatest extent practicable" [97.307(c)]. Further, if any spurious emission, including chassis or power-line radiation, causes harmful interference to the reception of another radio station, the licensee of the interfering amateur station is required to take steps to eliminate the interference.**

exa	E	$10^{18}$	= 1,000,000,000,000,000,000
peta	P	$10^{15}$	= 1,000,000,000,000,000
tera	T	$10^{12}$	= 1,000,000,000,000
giga	G	$10^9$	= 1,000,000,000
mega	M	$10^6$	= 1,000,000
kilo	k	$10^3$	= 1,000
hecto	h	$10^2$	= 100
deca	da	$10^1$	= 10
(unit)		$10^0$	= 1
deci	d	$10^{-1}$	= 0.1
centi	c	$10^{-2}$	= 0.01
milli	m	$10^{-3}$	= 0.001
micro	$\mu$	$10^{-6}$	= 0.000001
nano	n	$10^{-9}$	= 0.000000001
pico	p	$10^{-12}$	= 0.000000000001
femto	f	$10^{-15}$	= 0.000000000000001
atto	a	$10^{-18}$	= 0.000000000000000001

**Linear**

1 meter (m) = 100 centimeters (cm) = 1000 millimeters (mm)

**Area**

1 m<sup>2</sup> = 1 × 10<sup>4</sup> cm<sup>2</sup> = 1 × 10<sup>6</sup> mm<sup>2</sup>

**Volume**

1 m<sup>3</sup> = 1 × 10<sup>6</sup> cm<sup>3</sup> = 1 × 10<sup>9</sup> mm<sup>3</sup>

1 liter (l) = 1000 cm<sup>3</sup> = 1 × 10<sup>6</sup> mm<sup>3</sup>

**Mass**

1 kilogram (kg) = 1000 grams (g)

(Approximately the mass of 1 liter of water)

1 metric ton (or tonne) = 1000 kg

*U S Customary Units***Linear Units**

12 inches (in) = 1 foot (ft)

36 inches = 3 feet = 1 yard (yd)

1 rod = 5½ yards = 16½ feet

1 statute mile = 1760 yards = 5280 feet

1 nautical mile = 6076.11549 feet

**Area**

1 ft<sup>2</sup> = 144 in<sup>2</sup>

1 yd<sup>2</sup> = 9 ft<sup>2</sup> = 1296 in<sup>2</sup>

1 rod<sup>2</sup> = 30¼ yd<sup>2</sup>

1 acre = 4840 yd<sup>2</sup> = 43,560 ft<sup>2</sup>

1 acre = 160 rod<sup>2</sup>

1 mile<sup>2</sup> = 640 acres

**Volume**

1 ft<sup>3</sup> = 1728 in<sup>3</sup>

1 yd<sup>3</sup> = 27 ft<sup>3</sup>

**Liquid Volume Measure**

1 fluid ounce (fl oz) = 8 fluidrams = 1.804

1 pint (pt) = 16 fl oz

1 quart (qt) = 2 pt = 32 fl oz = 57¾ in<sup>3</sup>

1 gallon (gal) = 4 qt = 231 in<sup>3</sup>

1 barrel = 31½ gal

**Dry Volume Measure**

1 quart (qt) = 2 pints (pt) = 67.2 in<sup>3</sup>

1 peck = 8 qt

1 bushel = 4 pecks = 2150.42 in<sup>3</sup>

**Avoirdupois Weight**

1 dram (dr) = 27.343 grains (gr) or (gr a)

1 ounce (oz) = 437.5 gr

1 pound (lb) = 16 oz = 7000 gr

1 short ton = 2000 lb, 1 long ton = 2240 lb

**Troy Weight**

1 grain troy (gr t) = 1 grain avoirdupois

1 pennyweight (dwt) or (pwt) = 24 gr t

1 ounce troy (oz t) = 480 grains

1 lb t = 12 oz t = 5760 grains

**Apothecaries' Weight**

1 grain apothecaries' (gr ap) = 1 gr t = 1 gr

1 dram ap (dr ap) = 60 gr

1 oz ap = 1 oz t = 8 dr ap = 480 gr

1 lb ap = 1 lb t = 12 oz ap = 5760 gr

## Multiply →

Metric Unit = Conversion Factor × U.S. Customary Unit

## ← Divide

Metric Unit ÷ Conversion Factor = U.S. Customary Unit

# Common Schematic Symbols Used in Circuit Diagrams

## Abbreviations List

a—atto (prefix for $10^{-18}$ )	C—coulomb (quantity of electric charge); capacitor	DSB—double sideband
A—ampere (unit of electrical current)	CAC—Contest Advisory Committee	DSP—digital signal processing
ac—alternating current	CATV—cable television interference	DTMF—dual-tone multifrequency
ACC—Affiliated Club Coordinator	CB—Citizens Band (radio)	DVM—digital voltmeter
ACSSB—amplitude-compandored single sideband	CBBS—computer bulletin-board service	DX—long distance; duplex
A/D—analog-to-digital	CBMS—computer-based message system	DXAC—DX Advisory Committee
ADC—analog-to-digital converter	CCIR—International Research Consultative Committee	DXCC—DX Century Club
AF—audio frequency	CCITT—International Telegraph and Telephone Consultative Committee	
AFC—automatic frequency control	CCTV—closed-circuit television	e—base of natural logarithms (2.71828)
AFSK—audio frequency-shift keying	CCW—coherent CW	E—Voltage
AGC—automatic gain control	ccw—counterclockwise	EA—Educational Advisor
A/h—ampere hour	CD—civil defense	EC—Emergency Coordinator
AIRS—ARRL Interference Recording System	cm—centimeter	ECAC—Emergency Communications Advisory Committee
ALC—automatic level control	CMOS—complimentary-symmetry metal-oxide semiconductor	ECL—emitter-coupled logic
AM—amplitude modulation	coax—coaxial cable	EHF—extremely high frequency (30-300 GHz)
AMRAD—Amateur Radio Research and Development Corp	COR—carrier-operated relay	EIA—Electronic Industries Assn
AMSAT—Radio Amateur Satellite Corp	CP—code proficiency (award)	EIRP—effective isotropic radiated power
AMTOR—Amateur Teleprinting Over Radio	CPU—central processing unit	ELF—extremely low frequency
ANT—antenna	CRT—cathode ray tube	ELT—emergency locator transmitter
ARA—Amateur Radio Association	CT—center tap	EMC—electromagnetic compatibility
ARC—Amateur Radio Club	CTCSS—continuous tone-coded squelch system	EME—earth-moon-earth (moonbounce)
ARES—Amateur Radio Emergency Service	cw—clockwise	EMF—electromotive force
ARQ—Automatic repeat request	CW—continuous wave	EMI—electromagnetic interference
ARRL—American Radio Relay League		EMP—electromagnetic pulse
ARS—Amateur Radio Society (station)	d—deci (prefix for $10^{-1}$ )	EOC—emergency operations center
ASCII—American National Standard Code for Information Interchange	D—diode	EPROM—erasable programmable read only memory
ASSC—Amateur Satellite Service Council	da—deca (prefix for 10)	
ATV—amateur television	D/A—digital-to-analog	f—femto (prefix for $10^{-15}$ ); frequency
AVC—automatic volume control	DAC—digital-to-analog converter	F—farad (capacitance unit); fuse
AWG—American wire gauge	dB—decibel (0.1 bel)	fax—facsimile
az-el—azimuth-elevation	dBi—decibels above (or below) isotropic antenna	FCC—Federal Communications Commission
	dBm—decibels above (or below) one milliwatt	FD—Field Day
B—bel; blower; susceptance; flux density (inductors)	DBM—doubly balanced mixer	FEMA—Federal Emergency Management Agency
balun—balanced to unbalanced (transformer)	dBV—decibels above/below 1 V (in video, relative to 1 V P-P)	FET—field-effect transistor
BC—broadcast	dBW—decibels above/below 1 W	FFT—fast Fourier transform
BCD—binary coded decimal	dc—direct current	FL—filter
BCI—broadcast interference	D-C—direct conversion	FM—frequency modulation
Bd—baud (bit/s in single-channel binary data transmission)	DDS—direct digital synthesis	FMTV—frequency-modulated television
BER—bit error rate	DEC—District Emergency Coordinator	FSK—frequency-shift keying
BFO—beat-frequency oscillator	deg—degree	FSTV—fast-scan (real-time) television
bit—binary digit	DET—detector	ft—foot (unit of length)
bit/s—bits per second	DF—direction finding; direction finder	
BM—Bulletin Manager	DIP—dual in-line package	g—gram (unit of mass)
BPF—band-pass filter	DMM—digital multimeter	G—giga (prefix for $10^9$ ); conductance
BPL—Brass Pounders League	DPDT—double-pole double-throw (switch)	GaAs—gallium arsenide
BT—battery	DPSK—differential phase-shift keying	GDO—grid- or gate-dip oscillator
BW—bandwidth	DPST—double-pole single-throw (switch)	GHz—gigahertz ( $10^9$ Hz)
	DS—direct sequence (spread spectrum); display	GND—ground
c—centi (prefix for $10^{-2}$ )		
		h—hecto (prefix for $10^2$ )
		H—henry (unit of inductance)
		HF—high frequency (3-30 MHz)

HFO—high-frequency oscillator; heterodyne frequency oscillator	m—meter (length); milli (prefix for $10^{-3}$ )	OES—Official Emergency Station
HPF—highest probable frequency; high-pass filter	M—mega (prefix for $10^6$ ); meter (instrument)	OO—Official Observer
Hz—hertz (unit of frequency, 1 cycle/s)	mA—milliampere	op amp—operational amplifier
	mAh—milliamperehour	ORS—Official Relay Station
I—current, indicating lamp	MCP—multimode communications processor	OSC—oscillator
IARU—International Amateur Radio Union	MDS—Multipoint Distribution Service; minimum discernible (or detectable) signal	OSCAR—Orbiting Satellite Carrying Amateur Radio
IC—integrated circuit	MF—medium frequency (300-3000 kHz)	OTC—Old Timer's Club
ID—identification; inside diameter	mH—millihenry	OTS—Official Traffic Station
IEEE—Institute of Electrical and Electronics Engineers	MHz—megahertz	oz—ounce (force unit, 1/16 pound)
IF—intermediate frequency	mi—mile, statute (unit of length)	
IMD—intermodulation distortion	mi/h—mile per hour	p—pico (prefix for $10^{-12}$ )
in.—inch (unit of length)	mi/s—mile per second	P—power; plug
in./s—inch per second (unit of velocity)	mic—microphone	PA—power amplifier
I/O—input/output	min—minute (time)	PacTOR—digital mode combining aspects of packet and AMTOR
IRC—international reply coupon	MIX—mixer	PAM—pulse-amplitude modulation
ISB—independent sideband	mm—millimeter	PBS—packet bulletin-board system
ITF—Interference Task Force	MOD—modulator	PC—printed circuit
ITU—International Telecommunication Union	modem—modulator/demodulator	P <sub>D</sub> —power dissipation
	MOS—metal-oxide semiconductor	PEP—peak envelope power
j—operator for complex notation, as for reactive component of an impedance (+j inductive; -j capacitive)	MOSFET—metal-oxide semiconductor field-effect transistor	PEV—peak envelope voltage
J—joule (kg m <sup>2</sup> /s <sup>2</sup> ) (energy or work unit); jack	MS—meteor scatter	pF—picofarad
JFET—junction field-effect transistor	ms—millisecond	pH—picohenry
	m/s—meters per second	PIA—Public Information Assistant
k—kilo (prefix for $10^3$ ); Boltzmann's constant ( $1.38 \times 10^{-23}$ J/K)	msb—most-significant bit	PIN—positive-intrinsic-negative (semiconductor)
K—kelvin (used without degree symbol) (absolute temperature scale); relay	MSI—medium-scale integration	PIO—Public Information Officer
kBd—1000 bauds	MSK—minimum-shift keying	PIV—peak inverse voltage
kbit—1024 bits	MSO—message storage operation	PLL—phase-locked loop
kbit/s—1024 bits per second	MUF—maximum usable frequency	PM—phase modulation
kbyte—1024 bytes	mV—millivolt	PMOS—P-channel (metal-oxide semiconductor)
kg—kilogram	mW—milliwatt	PNP—positive-negative positive (transistor)
kHz—kilohertz	MΩ—megohm	pot—potentiometer
km—kilometer		P-P—peak to peak
kV—kilovolt	n—nano (prefix for $10^{-9}$ ); number of turns (inductors)	ppd—postpaid
kW—kilowatt	n—nano (prefix for $10^{-9}$ ); number of turns (inductors)	PRAC—Public Relations Advisory Committee
kΩ—kilohm	NBFM—narrow-band frequency modulation	PROM—programmable read-only memory
	NC—no connection; normally closed	PSHR—Public Service Honor Roll
l—liter (liquid volume)	NCS—net-control station; National Communications System	PTO—permeability-tuned oscillator
L—lambert; inductor	nF—nanofarad	PTT—push to talk
lb—pound (force unit)	NF—noise figure	
LC—inductance-capacitance	nH—nanohenry	Q—figure of merit (tuned circuit); transistor
LCD—liquid crystal display	NiCd—nickel cadmium	QRP—low power (less than 5-W output)
LED—light-emitting diode	NM—Net Manager	
LF—low frequency (30-300 kHz)	NMOS—N-channel metal-oxide silicon	R—resistor
LHC—left-hand circular (polarization)	NO—normally open	RACES—Radio Amateur Civil Emergency Service
LO—local oscillator; League Official	NPN—negative-positive-negative (transistor)	RAM—random-access memory
LP—log periodic	NPRM—Notice of Proposed Rule Making (FCC)	RC—resistance-capacitance
LS—loudspeaker	NR—Novice Roundup (contest)	R/C—radio control
lsb—least significant bit	ns—nanosecond	RCC—Rag Chewer's Club
LSB—lower sideband	NTS—National Traffic System	RDF—radio direction finding
LSI—large-scale integration		RF—radio frequency
LUF—lowest usable frequency	OBS—Official Bulletin Station	RFC—radio-frequency choke
	OD—outside diameter	RFI—radio-frequency interference

RHC—right-hand circular (polarization)	U—integrated circuit	°—degree (plane angle)
RIT—receiver incremental tuning	UHF—ultra-high frequency (300 MHz to 3 GHz)	°C—degree Celsius (temperature)
RLC—resistance-inductance-capacitance	USB—upper sideband	°F—degree Fahrenheit (temperature)
RM—rule making (number assigned to petition)	UTC—Coordinated Universal Time	$\alpha$ —(alpha) angles; coefficients, attenuation constant, absorption factor, area, common-base forward current-transfer ratio of a bipolar transistor
r/min—revolutions per minute	UV—ultraviolet	$\beta$ —(beta) angles; coefficients, phase constant current gain of common-emitter transistor amplifiers
RMS—root mean square	V—volt; vacuum tube	$\gamma$ —(gamma) specific gravity, angles, electrical conductivity, propagation constant
ROM—read-only memory	VCO—voltage-controlled oscillator	$\Upsilon$ —(gamma) complex propagation constant
r/s—revolutions per second	VCR—video cassette recorder	$\delta$ —(delta) increment or decrement; density; angles
RST—readability-strength-tone (CW signal report)	VDT—video-display terminal	$\Delta$ —(delta) increment or decrement determinant, permittivity
RTTY—radioteletype	VE—Volunteer Examiner	$\epsilon$ —(epsilon) dielectric constant; permittivity; electric intensity
RX—receiver, receiving	VEC—Volunteer Examiner Coordinator	$\zeta$ —(zeta) coordinates; coefficients
	VFO—variable-frequency oscillator	$\eta$ —(eta) intrinsic impedance; efficiency; surface charge density; hysteresis; coordinate
s—second (time)	VHF—very-high frequency (30-300 MHz)	$\theta$ —(theta) angular phase displacement; time constant; reluctance; angles
S—siemens (unit of conductance; switch)	VLf—very-low frequency (3-30 kHz)	$\iota$ —(iota) unit vector
SASE—self-addressed stamped envelope	VLSI—very-large-scale integration	K—(kappa) susceptibility; coupling coefficient
SCF—switched capacitor filter	VMOS—V-topology metal-oxide semiconductor	$\lambda$ —(lambda) wavelength; attenuation constant
SCR—silicon controlled rectifier	VOM—volt-ohm meter	$\Lambda$ —(lambda) permeance
SEC—Section Emergency Coordinator	VOX—voice operated switch	$\mu$ —(mu) permeability; amplification factor; micro (prefix for $10^{-6}$ )
SET—Simulated Emergency Test	VR—voltage regulator	$\mu C$ —microcomputer
SGL—State Government Liaison	VRAC—VHF Repeater Advisory Committee	$\mu F$ —microfarad
SHF—super-high frequency (3-30 GHz)	VSWR—voltage standing-wave ratio	$\mu H$ —microhenry
SM—Section Manager; silver mica (capacitor)	VTVM—vacuum-tube voltmeter	$\mu P$ —microprocessor
S/N—signal-to-noise ratio	VUAC—VHF/UHF Advisory Committee	$\xi$ —(xi) coordinates
SPDT—single pole double-throw (switch)	VUCC—VHF/UHF Century Club	$\pi$ —(pi) 3.14159
SPST—single-pole single-throw (switch)	VXO—variable-frequency crystal oscillator	$\rho$ —(rho) resistivity; volume charge density; coordinates; reflection coefficient
SS—Sweepstakes; spread spectrum		$\sigma$ —(sigma) surface charge density; complex propagation constant; electrical conductivity; leakage coefficient; deviation
SSB—single sideband	W—watt ( $\text{kg m}^2\text{s}^{-3}$ ), unit of power	$\Sigma$ —(sigma) summation
SSC—Special Service Club	WAC—Worked All Continents	$\tau$ —(tau) time constant; volume resistivity; time-phase displacement; transmission factor; density
SSI—small-scale integration	WAS—Worked All States	$\phi$ —(phi) magnetic flux; angles
SSTV—slow-scan television	WBFM—wide-band frequency modulation	$\Phi$ —(phi) summation
STM—Section Traffic Manager	WEFAX—weather facsimile	$\chi$ —(chi) electric susceptibility; angles
SX—simplex	Wh—watthour	$\psi$ —(psi) dielectric flux; phase difference; coordinates; angles
sync—synchronous, synchronizing	WPM—words per minute	$\omega$ —(omega) angular velocity $2\pi f$
SWL—shortwave listener	WRC—World Radio Conference	$\Omega$ —(omega) resistance in ohms; solid angle
SWR—standing-wave ratio	WVDC—working voltage, direct current	
T—tera (prefix for $10^{12}$ ); transformer	X—reactance	
TA—Technical Advisor	XCVR—transceiver	
TC—Technical Coordinator	XFMR—transformer	
TCC—Transcontinental Corps (NTS)	XIT—transmitter incremental tuning	
TCP/IP—Transmission Control Protocol/Internet Protocol	XO—crystal oscillator	
TD—Technical Department (ARRL HQ)	XTAL—crystal	
tfc—traffic	XVTR—transverter	
TNC—terminal node controller (packet radio)		
TR—transmit/receive	Y—crystal; admittance	
TS—Technical Specialist	YIG—yttrium iron garnet	
TTL—transistor-transistor logic		
TTY—teletypewriter	Z—impedance; also see UTC	
TU—terminal unit		
TV—television	5BDXCC—Five-Band DXCC	
TVI—television interference	5BWAC—Five-Band WAC	
TX—transmitter, transmitting	5BWAS—Five-Band WAS	
	6BWAC—Six-Band WAC	

## ARRL Handbook Address List

These companies or individuals are cited in this edition of the *ARRL Handbook*. Please send updates to the ARRL Handbook Editor at ARRL Headquarters.

A & A Engineering  
2521 W LaPalma Ave, Unit K  
Anaheim, CA 92801  
714-952-2114  
fax 714-952-3280

Advanced Electronic Applications, Inc  
PO Box C2160  
Lynnwood, WA 98036  
206-774-5554  
800-432-8873 (literature requests)  
206-775-7373 (service)

Advanced Receiver Research  
Box 1242  
Burlington, CT 06013  
203-485-0311

Alexander Aeroplane Co  
PO Box 909  
Griffin, GA 30224

## Technical Information Packages

The following is a list of information packages that are available to League members to provide assistance for technical problems and introductory information on topics of interest. To request copies of these packages, send a separate written request to the ARRL Technical Department Secretary. Include a 9x12 self-addressed envelope with 3 units of First Class postage for each package desired.

Most of these packages are also available electronically from the following sources:

1. The ARRL Field Services telephone BBS. The BBS can be reached by dialing 203-594-0306, utilizing standard 8-n-1 parameters, connect rates from 300 baud up to 14,400 baud.
2. Electronic Mail: From CompuServe, Prodigy, America Online and similar services, you can send email to the League's Internet Email Information Server. Send a message to [info@arrl.org](mailto:info@arrl.org) (this is an Internet address; contact your service provider for details on sending email to Internet). In the text of your message, write the single word HELP to get a set of instructions for using this service.
3. File Transfer Protocol (FTP - Internet only). The League has a remote FTP archive site that contains all of the files from the email server. For the current address of this site, FTP to [mgate.arrl.org](ftp://mgate.arrl.org) and retrieve the file [helpinfo.txt](#).

<b>Title</b>	<b>Description</b>	<b>Title</b>	<b>Description</b>
ATV	Information about Fast-Scan Amateur Television	G5RV	Bibliography of G5RV articles, and reprint from Antenna Compendium I
Bioeffects	Bioeffects of RF Energy (Reprint from ARRL Antenna Book)	Grid Squares	How to Locate them (Reprint from January 1989 QST, p 29)
BIBS-List	Listing of bibliographies available from the ARRL	Indoor Antennas	Select an Indoor Antenna (Reprint from QST, December 1992 Lab Notes)
CX-857 Data Sheets	AM Stereo Decoding IC Data (for September 1992 QEX article)	Kits	ARRL Kit Mfg. List
DSP	General information on Digital Signal Processing	LCF Calculator	Copy of an old out-of-print LCF Calculator
Electrical Safety	Reprint from ARRL Antenna Book (pp 1-8 to 1-16)	Lightning Protection Manuals	Reprint of two-part Lab Notes column How to Locate Manuals and Documentation
Emergency Power	Reference to QST, April 1993 Lab Notes	Mobile - Marine	Maritime Mobile Installation suggestions
EMI/RFI Pckg.	General information about EMI/RFI	Moonbounce/EME	Information about moonbounce (Reprint from QST, July 1985, pp 18-21)
EMI - Audio	Interference to audio equipment	Packet Parts List	Ch. 35 of Hbk. & QST, August 1992 Lab Notes
EMI - Automotive	Automotive Interference solutions	Printed Circuit Boards	Sources for PCB prototypes and supplies
EMI - Bibliography	List of QST articles about interference	Propagation Basics	Propagation Introduction and Terms explained
EMI - CATVI	Interference to Cable Television Systems (Reprints from Communications Technology)	RDF	Radio Direction Finding
EMI - CB	Interference from Non-Amateur Transmitters	Receiver Tests	Technical Descriptions
EMI - Computer	Brief suggestions	RIG	What Rig Should I Buy? (Reprints from QST)
EMI - Consumer	Consumer Pamphlet on RFI	RTTY/AMTOR	Getting Started with HF Digital Communications
EMI - Electrical	How to track and solve electrical interference	Satellites	Information about amateur satellite operation
EMI - Ignition	Suggestions for solving ignition noise RFI	Software	Reference to QST, April 1992 Lab Notes
EMI - Intercom	Nutone RFI service bulletins	SSTV	Reprint from QST, January 1993, p 20
EMI - Pacemaker	Susceptibility of Cardiac Pacemakers to interference	Stores	US stores that sell amateur radio equipment
EMI - RF Bulbs	Information about RF-driven lamps	Synchronous Detection	Reprint from QEX, September 1992, p 9
EMI - Smoke Detector	Interference to Smoke Detectors (Reprints from QST)	SWL Tips	General information about short-wave listening
EMI - Telephone/FCC	FCC Information Bulletin on Telephone Interference	TCP/IP	Getting Started with Amateur TCP/IP
EMI - Telephones	Reprint from QST, October 1992 Lab Notes	TV Channels - CATV	General Information
EMI - Television	Reprint from QST, March 1994 Lab Notes	Vacuum Tube Data	General Information
EMI - Touch Lamp	Various QST Hints & Kinks reprints	WEFAX	Reprint from QST, February 1993, pp 31-36
EMI - VCR	Brief suggestions (see note 2)		
Frequency Counter	Reprint of 93 Hbk (pp 25-13 to 25-19) —Frequency Counter article		

## Technical Information Packages (continued)

### Article Bibliographies

The following items are lists of articles from many Amateur Radio magazines and other related publications by subject.

<i>File Name</i>	<i>Description</i>	<i>File Name</i>	<i>Description</i>
altpwr.txt	Alternate power	ibm.txt	Computers, IBM
amtor.txt	AMTOR Articles	ic.txt	Integrated Circuits
ant16040.txt	Antennas, 160-40 Meter	icom.txt	ICOM equipment & mods
ant3010.txt	Antennas, 30-10 Meter	kenwood.txt	Kenwood equipment and mods
antcurt.txt	Antennas, curtain type	keyer.txt	Keys, keyers and keying
antjpole.txt	Antennas, J-Pole	lghtnbib.txt	Lightning
antlimsp.txt	Antennas, limited space	light.txt	Laser Communications
antlog.txt	Antennas, log periodic	mfi.txt	MFJ products
antloop.txt	Antennas, Loop	microwv.txt	Microwave Operation
antmatch.txt	Antennas, Matching	nbvm.txt	NBVM
antmobil.txt	Antennas, Mobile	oscope.txt	Oscilloscopes
antrot.txt	Antenna Rotators	packbib.txt	Packet Radio
antswltc.txt	Antenna Switchers	pactor.txt	PacTOR (Digital Mode)
anttheor.txt	Antenna Theory	pcbrd.txt	Printed circuit boards
antvee.txt	Antennas, V	prog.txt	Computers, Programs
antvert.txt	Antennas, Vertical	projacc.txt	Station Accessories Proj.
antvhf.txt	Antennas, VHF and up	prop.txt	Propagation
apple.txt	Computers, APPLE	public.txt	Public Service communications
atari.txt	Computers, ATARI	pwrstupp.txt	Power Supplies
atv.txt	Amateur Fast-Scan Television (ATV)	qrp.txt	QRP - Articles on low power
basconst.txt	Basic Construction	radastro.txt	Radio Astronomy
baselect.txt	Basic Electronics	rcvrhf.txt	Receivers, HF
battery.txt	Batteries, Nicads and Chargers	rcvrvhf.txt	Receivers, VHF and up
bc221.txt	BC-221	remote.txt	Remote Control
bicycle.txt	Bicycle Operating	rft.txt	Radio Frequency Interference (RFI)
bioeff.txt	Bio-effects of RF Energy	rftpcmk.txt	RFI, Pacemaker
cbconv.txt	CB Conversion to 10 Meters	rptr.txt	Repeaters
clover.txt	Clover (Digital Protocol)	rtty.txt	Radio TeleTYpe (RTTY)
coax.txt	Coax cables and feedlines	safety.txt	Safety
collins.txt	Collins equipment	sarex.txt	Shuttle Amateur Radio Experiment
compgen.txt	Computers, general	satbib.txt	Satellite (amateur)
contest.txt	Contesting	speech.txt	Speech Processing
crystal.txt	Crystals	spread.txt	Spread Spectrum
ctcssbib.txt	CTCSS	sstvbib.txt	Slow-Scan Television
dfing.txt	Direction finding, Radio (RDF)	surface.txt	Surface Mount Devices
diverse.txt	Diversity Reception	surplus.txt	Surplus Equipment
drake.txt	Drake Equipment	swr.txt	SWR/Power Meters
dsp.txt	Digital Signal Processing	synth.txt	Synthesizers
dtmf.txt	DTMF - tone decoders	tentec.txt	Ten Tec products
echo.txt	Echoes (includes LDE)	testeapt.txt	Test equipment
eme.txt	Earth-Moon-Earth Communications	time.txt	Time Signals
esd.txt	Electro-static discharge	tower.txt	Towers/tower safety
fax.txt	Amateur FAX/WEFAX	trs.txt	Computers, Radio Shack
fiber.txt	Fiber Optics	tv.txt	Television
filteraf.txt	Filters, audio	up.txt	Computers, microprocessor
filterif.txt	Filters, IF	vic.txt	Computers, VIC and Commodore
filterrf.txt	Filters, RF	vlf.txt	Very Low Frequency (VLF)
grounds.txt	Grounds	warc.txt	WARC Band equipment
handicap.txt	Handicap (suitable equip.)	weaksig.txt	Weak signal reception
heath.txt	Heathkit	xmtrhf.txt	Transmitters, HF
historic.txt	Historical References	xmtrvhf.txt	Transmitters, VHF and up
hmbrwcmp.txt	Homebrew Components	yaesu.txt	Yaesu equipment and mods

## Publishers and Publications

The following is a list of publishers, periodicals, books and book sources dealing with Amateur Radio and other related topics. Contact information appears in the *ARRL Handbook* Address List elsewhere in this chapter. Send updates to the Handbook Editor at ARRL Headquarters.

AM Press/Exchange  
 Amateur Television Quarterly  
 AMECO Publishing  
 American Radio Relay League (ARRL)  
 AMSAT  
 Antique Radio Classified  
 Buckmaster Publishing  
 Communications Quarterly  
 CQ Magazine  
 CQ-TV  
 Digital Journal  
 Dots and Dashes  
 Electric Radio Magazine  
 Electronic Industries Assn  
 Electronics Now/Radio Electronics  
 Grove Enterprises  
 Ham Equipment Buyers Guide  
 Ham Trader Yellow Sheets  
 Howard W. Sams  
 Idiom Press  
 IEEE  
 The Lowdown (Long Wave Club of America)  
 MFJ  
 Model Aviation (Radio Control)  
 Monitoring Times  
 Motorola Literature Distribution Center (data books)  
 Nuts & Volts Magazine  
 Old Tech—Books & Things (early technical books)  
 Old Timer's Bulletin  
 Osborne/McGraw-Hill  
 Popular Communications  
 Practical Wireless  
 QRP Quarterly  
 Radio Age (Antique Radio)  
 Radio Communication (RSGB)  
 Rainy Day Books (radio and technical books)  
 Short Wave Magazine  
 Sky & Telescope (Astronomy)  
 Sparks Journal  
 SPEC-COM Journal  
 TAB/McGraw-Hill  
 TAPR  
 United Nations Bookstore  
 VISION  
 Weatherwise (Meteorology)  
 Weekly Ham Trader  
 Worldradio  
 W5YI Group  
 73 Amateur Radio Today

39	0.003531	—	—
40	0.003145	—	—

All dimensions are in inches.

<sup>†</sup>Used for aluminum, copper, brass and nonferrous alloy sheets, wire and rods.

<sup>††</sup>Used for iron, steel, nickel and ferrous alloy sheets, wire and rods.

<sup>†††</sup>Used for seamless tubes; also by some manufacturers for copper and brass.

Based on a 50-ohm system

Voltage			Power	
RMS	Peak-to-Peak	dBmV	Watts	dBm
0.01 $\mu$ V	0.0283 $\mu$ V	-100	$2 \times 10^{-18}$	-147.0

	4	1.0
	6	2.3
	8	4.2
	10	6.6
	16	16.9
	32	68

Factor to be applied to the inductance of coils listed in 30.16, as a function of coil length. Use curve A for coils marked A, and curve B for coils marked B.

Measured inductance of coils wound with no. 12 bare wire, eight turns per inch. The values include half-inch leads.

Detailed instructions for using these tables appear in the **Filters** chapter. If you are unfamiliar with filter design from tables, look there to learn the basics. This simple example is intended as a memory aid, not a tutorial.

Let's design a low-pass filter for a 20-m CW transmitter. Based on measurements of the second harmonic, insertion loss (attenuation) should be at least 20 dB at the minimum second-harmonic frequency (28 MHz). Insertion loss should be minimal at the maximum operating frequency (14.1 MHz).

When choosing a filter, look for appropriate cutoff and attenuation frequencies, but *ignore the decimal points* because the component values are easily scaled by powers of ten. A 5-element Chebyshev design (see Item 30.20) looks like a good choice because designs 20 through 22 show 20-dB frequencies of 2.73 and 2.77 MHz and cutoff frequencies of 1.44 to 1.66 MHz. In fact, those numbers are *too* close to our targets (27.7 MHz is only 1.1% under 28 MHz). Using 5% components, we would be lucky to get within 5% of the design targets. It's better to move each target value 10% or so to the safe side, which yields 20 dB at 25.2 MHz and  $f_{co} = 15.5$  MHz rolloff. No 5-element design in the table can meet these criteria.

In the 7-element Chebyshev list (Item 30.22), however, design 25 meets the needs. It has a maximum SWR of 1.099:1, which is acceptable.

#### FREQUENCY (MHz)

NO.	$F_{co}$	3 dB	20 dB	40 dB	SWR	C1,7 (pF)	L2,6 (μH)	C3,5 (pF)	L4 (μH)
25	1.68	1.93	2.35	3.03	1.099	1500	6.58	3300	7.72

Scaling the filter is easy. We need only divide one of the frequencies listed into the desired frequency, round to the nearest power of ten and multiply all frequencies and divide all component values by the result:

$28/2.35 = 11.91$ , say 10; which gives:

#### FREQUENCY (MHz)

NO.	$F_{co}$	3 dB	20 dB	40 dB	SWR	C1,7 (pF)	L2,6 (μH)	C3,5 (pF)	L4 (μH)
25	16.8	19.3	23.5	30.3	1.099	150	0.658	330	.772

In some cases, the filter terminating impedances may not be 50 Ω. Then we need to adjust the filter values to match the required impedance. All tabulated designs are easily scaled to impedance levels other than 50 Ω, while keeping the convenience of standard-value capacitors and the "scan mode" of design selection. If the desired new impedance level differs from 50 Ω by a factor that is some power of ten, the 50-Ω design is scaled by shifting the decimal points of the component values, that is multiplying or dividing by some power of ten. The other data remain unchanged. For example, if the impedance level is increased by ten or one hundred times (to 500 or 5000 Ω), the decimal point of the capacitor is shifted to the left (dividing) one or two places and the decimal point of the inductor is shifted to the right (multiplying) one or two places. With increasing impedance, capacitor values decrease and inductor values increase. The opposite is true when impedance decreases.

When the desired impedance level differs from the standard 50-Ω value by a factor that is not a power of ten, such as 1.2, 1.5 or 1.86, the search criteria to select the design number must be adjusted by that factor:

1. Calculate the impedance scaling ratio:

$$R = \frac{Z_x}{50} \quad (1)$$

where  $Z_x$  is the desired new impedance level, in ohms.

2. Calculate the cutoff frequency ( $f_{50co}$ ) of a "trial" 50-Ω filter,

$$f_{50co} = R \times f_{xco} \quad (2)$$

where  $R$  is the impedance scaling ratio and  $f_{xco}$  is the desired cutoff frequency of the filter at the new impedance level.

3. Select a design from the SVC tables based on the calculated  $f_{50co}$ . The capacitor values of this design are taken directly, but the frequency and inductor values must be scaled to the new impedance level.

4. Calculate the exact  $f_{xco}$  values, where

$$f_{xco} = \frac{f'_{50co}}{R} \quad (3)$$

and  $f'_{50co}$  is the tabulated cutoff frequency of the selected design. Calculate the other frequencies of the design in the same way.

5. Calculate the inductor values for the new filter by multiplying the tabulated inductor values of the selected design by the square of the scaling ratio,  $R$ .

For example, assume that our 20-m low-pass filter were to be used in a 1000-Ω IF stage. This requires that we apply both methods, because a change from 50 to 1000 involves factors of 10 and 2 ( $50 \times 2 \times 10 = 1000$ ). Therefore, we must first scale the desired frequencies by from 50 Ω to 100 Ω ( $50 \times 2 = 100$ ):

$$R = 100/50 = 2$$

$$f_{50co} = 2 \times 15.5 = 31 \text{ MHz}$$

$$f_{-20dB} = 2 \times 25.2 = 50.4 \text{ MHz}$$

Select a filter based on these two values. Design 59 from the 7-element low-pass Chebyshev list looks good.

Scale all frequencies of the final design by dividing the tabulated frequencies impedance scaling ratio, 2:

$$f_{co} = 3.3/2 = 1.65$$

$$f_{-20dB} = 4.81/2 = 2.405$$

The inductor values are scaled to 100 Ω by multiplying them by the square of the impedance ratio, where  $R = 2$  and  $R^2 = 4.0$ :

$$L_{2,6} = 4.0 \times 3.24 \mu\text{H} = 12.96 \mu\text{H}$$

$$L_4 = 4.0 \times 3.88 \mu\text{H} = 15.52 \mu\text{H}$$

The 100-Ω design is now impedance scaled to 1000 Ω by shifting the decimal points of the capacitor values to the left and the decimal points of the inductor values to the right. The final scaled component values for the 1000-Ω filter are:

$$C_{1,7} = 68 \text{ pF}$$

$$C_{3,5} = 160 \text{ pF}$$

$$L_{2,6} = 129.6 \mu\text{H}$$

$$L_4 = 155.2 \mu\text{H}$$

## 5-Element Chebyshev Low-Pass Filter Designs

### 50-Ohm Impedance, C-In/Out for Standard E24 Capacitor Values

Filter No.	Frequency (MHz)				Max. SWR	C1,5 (pF)	L2,4 (μH)	C3 (pF)	Filter No.	Frequency (MHz)				Max. SWR	C1,5 (pF)	L2,4 (μH)	C3 (pF)

National Tower Co  
Rohn  
Texas Towers  
Tri-Ex Tower Corp  
Universal Manufacturing Co  
US Tower Corp

### 30.32

#### Antenna Wire Strength

American Wire Gauge	Recommended Tension <sup>1</sup> (pounds)		Weight (pounds per 1000 feet)	
	Copper-clad steel <sup>2</sup>	Hard-drawn copper	Copper-clad steel <sup>2</sup>	Hard-drawn Copper
4	495	214	115.8	126
6	310	130	72.9	79.5
8	195	84	45.5	50
10	120	52	28.8	31.4
12	75	32	18.1	19.8
14	50	20	11.4	12.4
16	31	13	7.1	7.8
18	19	8	4.5	4.9
20	12	5	2.8	3.1

<sup>1</sup>Approximately one-tenth the breaking load. Might be increased 50 percent if end supports are firm and there is no danger of ice loading.

<sup>2</sup>"Copperweld," 40 percent copper.

## Standard Sizes of Aluminum Tubing

6061-T6 (61S-T6) round aluminum tube in 12-ft lengths

44	0.0032	40
46	0.0024	—

## Impedance of Various Two-Conductor Lines

Wire Size	Twists per Inch				
	2½	5	7½	10	12½
no. 20	43	39	35		
no. 22	46	41	39	37	32
no. 24	60	45	44	43	41
no. 26	65	57	54	48	47
no. 28	74	53	51	49	47
no. 30			49	46	47

Measured in ohms at 14.0 MHz

This chart illustrates the impedance of various two-conductor lines as a function of the wire size and number of twists per inch.

## Attenuation per Foot for Lines in 30.35

Wire Size	Twists per Inch				
	2½	5	7½	10	12½
no. 20	0.11	0.11	0.12		
no. 22	0.11	0.12	0.12	0.12	0.12
no. 24	0.11	0.12	0.12	0.13	0.13
no. 26	0.11	0.13	0.13	0.13	0.13
no. 28	0.11	0.13	0.13	0.16	0.16
no. 30			0.25	0.27	0.27

Measured in decibels at 14.0 MHz

Attenuation in dB per foot for the same lines as shown in 30.35.

## Equivalent Values of Reflection Coefficient, Attenuation, SWR and Return Loss

Reflection Coefficient (%)	Attenuation (dB)	Max. SWR	Return Loss (dB)	Reflection Coefficient (%)	Attenuation (dB)	Max. SWR	Return Loss (dB)	Reflection Coefficient (%)	Attenuation (dB)	Max. SWR	Return Loss (dB)

$$\rho = \frac{\text{SWR} - 1}{\text{SWR} + 1}$$

where  $\rho = 0.01 \times$  (reflection coefficient in %)

$$\rho = 10^{-\frac{\text{RL}}{20}}$$

where RL = return loss (dB)

$$\rho = \sqrt{1 - (0.1^X)}$$

where X = A/10 and A = attenuation (dB)

$$\text{SWR} = \frac{1 + \rho}{1 - \rho}$$

Return loss (dB) =  $-8.68589 \ln(\rho)$

where  $\ln$  is the natural log (log to the base e)

Attenuation (dB) =  $-4.34295 \ln(1 - \rho^2)$

where  $\ln$  is the natural log (log to the base e)

The black bars indicate ungrounded guy wire lengths to avoid for the eight HF amateur bands. This chart is based on resonance within 10% of any frequency in the band. Grounded wires will exhibit resonance at odd multiples of a quarter wavelength. (Jerry Hall, K1TD)

## Notes

- Not all Morse characters shown are used in FCC code tests. License applicants are responsible for knowing, and may be tested on, the 26 letters, the numerals 0 to 9, the period, the comma, the question mark, AR, SK, BT and fraction bar [DN].
- The following letters are used in certain European languages which use the Latin alphabet:

Ä, A	didahdidah	..---	Ö, Ö, Ó	dahdahdahdit	---..
Å, Ä, Å, Ä	didahdahdidah	..---	Ñ	dahdahdidahdah	---..
Ç, C	dahdidahdidit	---..	Ü	didididah	---..
È, È, È	dididahdidit	---..	Ž	dahdahdidit	---..
É	didahdididit	---..	Ž	dahdahdididit	---..
Ê	dahdididahdit	---..	CH, Ş	dahdahdahdah	---

## 3. Special Esperanto characters:

Ĉ	dahdidahdidit	---..
Ĉ	didididahdit	---..
Ĥ	didahdahdahdit	---..
Ĥ	dahdidahdahdit	---..
Ŭ	didididah	---..

## 4. Signals used in other radio services:

Interrogatory	dididahdidah	---..	INT
Emergency silence	dididididahdah	---..	FM
Executive follows	dididahdididit	---..	IX
Break-in signal	dahdahdahdahdah	---	TTTT
Emergency signal	didididahdahdahdidit	---..	SOS
Relay of distress	dahdididahdididahdit	---..	DDD

Numeral	Long Number	Cut Number	Equivalent Character
1	didahdahdahdah	didah	A
2	dididahdahdah	dididah	U
3	didididahdah	didididit	V
4	dididididit	dididididit	4
5	dididididit	dididididit	5 or E
6	dahdidididit	dahdidididit	6
7	dahdahdididit	dahdididit	B
8	dahdahdahdidit	dahdidit	D
9	dahdahdahdahdit	dahdit	N
0	dahdahdahdahdah	dah	T

Note: These abbreviated numbers are not legal for use in call signs. They should be used only where there is agreement between operators and when no confusion will result.

## Notes

<sup>1</sup> represents the mark condition (shown as Z in ITU recommendations) which is the higher emitted radio frequency for FSK, the lower audio frequency for AFSK. 0 represents the space condition (shown as A in ITU documents). Bits are numbered 0 (least significant bit) through 4 (most-significant bit). The order of bit transmission is LSB first, MSB last. Symbols A and Z are defined in CCIR Rec. R.140.

<sup>2</sup> represents the mark condition (shown as B in CCIR recommendations), which is the higher emitted radio frequency for FSK, the lower audio frequency for AFSK. 0 represents the space condition (shown as Y in CCIR recommendations). Bits are numbered 0 (LSB) through 6 (MSB). The order of bit transmission is LSB first, MSB last.

<sup>3</sup> Many U.S. teletypewriters have these figures case characters.

<sup>4</sup> At present unassigned. Reception of these signals, however, should not initiate a request for repetition.

<sup>5</sup> The pictorial representations of ☐ or ✱ indicate WRU (Who are you?), which is used for an answer-back function in telex networks.

## Baudot Signaling Rates and Speeds

Signaling Rate (bauds)	Data Pulse (ms)	Stop Pulse (ms)	Speed (WPM)	Common Name
45.45	22.0	22.0	65.00	Western Union
	22.0	31.0	61.33	"60 speed"
	22.0	33.0	60.61	45 bauds
50.00	20.0	30.0	66.67	European; 50 bauds
56.92	17.57	25.00	76.68	"75 speed"
	17.57	26.36	75.89	57 bauds
74.20	13.47	19.18	100.00	"100 speed"
	13.47	20.21	98.98	74 bauds
100.0	10.00	15.00	133.33	100 bauds

## The ASCII Coded Character Set

CR	= carriage return	LF	= line feed
DC1	= device control 1	NAK	= negative acknowledge
DC2	= device control 2	NUL	= null
DC3	= device control 3	RS	= record separator
DC4	= device control 4	SI	= shift in
DEL	= (delete)	SO	= shift out
DLE	= data link escape	SOH	= start of heading
ENQ	= enquiry	SP	= space
EM	= end of medium	STX	= start of text
EOT	= end of transmission	SUB	= substitute
ESC	= escape	SYN	= synchronous idle
ETB	= end of block	US	= unit separator
ETX	= end of text	VT	= vertical tab

## Notes

1. "1" = mark, "0" = space.
2. Bit 6 is the most-significant bit (MSB).  
Bit 0 the least-significant bit (LSB).

Note 1: For complete specifications of these codes see the following International Telecommunication Union documents: ITA1 and 2 — Telegraph Regulations (Geneva Revision, 1958), ITA3 — CCITT Rec. S.13, ITA4 — CCITT Rec. R.44.

Note 2: In ITA1, + indicates positive current, — negative current. In ITA2 through ITA4, 1 represents mark condition (shown as Z in ITU recommendations, which is the higher emitted radio frequency for FSK, the lower for AFSK). 0 represents the space condition (shown

as A in ITU recommendations). For meanings of A and Z see CCITT Rec. 140. The normal order of bit transmission is lowest significant bit (LSB) first.

Note 3: At the disposal of each administration for its internal service.

Note 4: At present unassigned. Reception of these signals, however, should not initiate a request for repetition. See CCITT Rec. S.4.

Note 5: Permanent 0 polarity.

Note 6: Permanent 1 polarity.

## Data Interface Connections

Pin	Ckt	EIA-232-D Description	V.24 No.	Name	Common Abbr.*

## ISO 2593 Pin Allocations for V.35 Interfaces

Pin	Circuit	Direction	Function
A	101	Common	Protective ground or earth
B	102	Common	Signal ground or common return
C	105	from DTE	Request to send
D	106	to DTE	Ready for sending
E	107	to DTE	Data set ready
F	109	from DTE	Data channel received line signal detector
H	108/1	from DTE	Connect data set to line
	108/2	from DTE	Data terminal ready
	125	to DTE	Calling indicator
K	—	—	F <sub>1</sub>
L	—	—	F <sub>2</sub>
M	—	—	F <sub>1</sub>
N	—	—	F <sub>2</sub>
R	104	to DTE	Received data A-wire
T	104	to DTE	Received data B-wire
V	115	to DTE	Receiver signal element timing A-wire
X	115	to DTE	Receiver signal element timing B-wire
Y	114	to DTE	Transmitter signal element timing A-wire

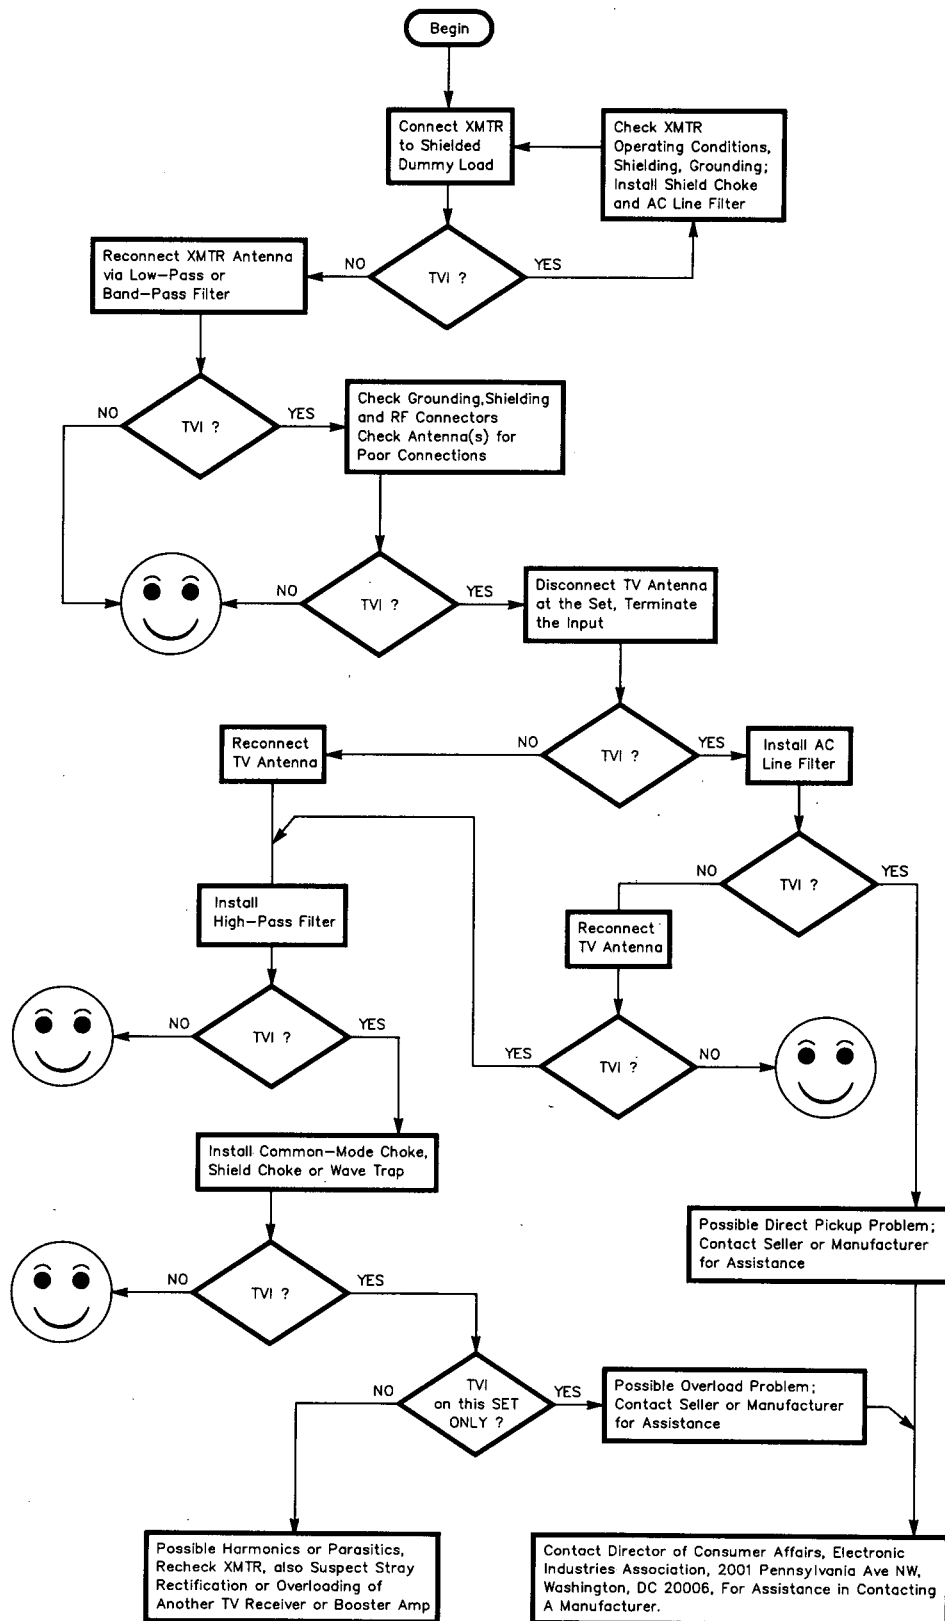

N = Pins permanently reserved for national use.  
Pins HH, JJ and KK are used in the U.K. for transmitter-clock control.

Pin	Circuit	Direction	Function
AA	114	to DTE	Transmitter signal element timing B-wire
P	103	from DTE	Transmitted data A-wire
S	103	from DTE	Transmitted data B-wire
U	113	from DTE	Transmitter signal element timing A-wire
Z	—	—	F <sub>3</sub>
W	113	from DTE	Transmitter signal element timing B-wire
BB	—	—	F <sub>3</sub>
CC	—	—	F <sub>4</sub>
DD	—	—	F <sub>5</sub>
EE	—	—	F <sub>4</sub>
FF	—	—	F <sub>5</sub>
HH	—	—	N <sub>1</sub>
JJ	—	—	N <sub>2</sub>
KK	—	—	N <sub>1</sub>
LL	—	—	N <sub>2</sub>
MM	—	—	F
NN	—	—	F

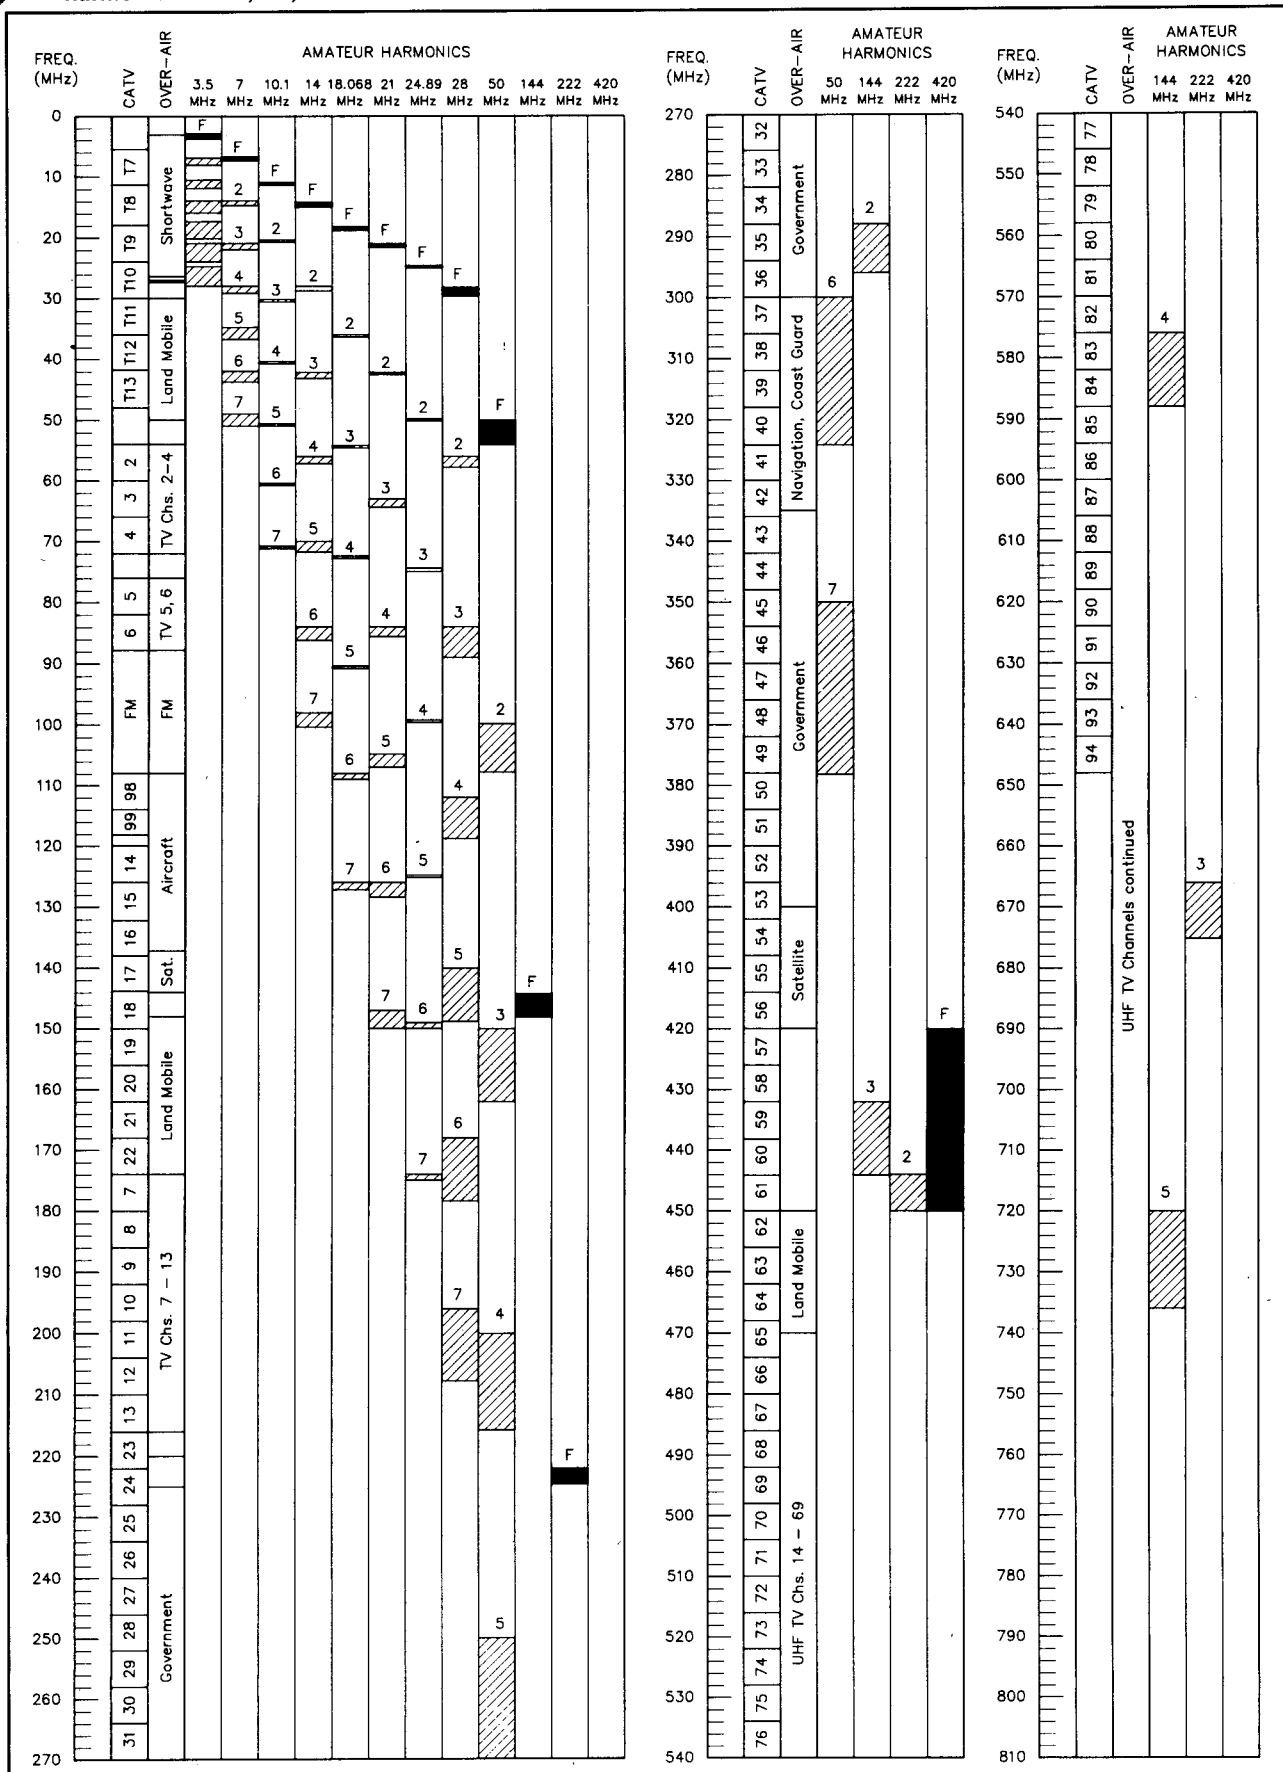

F = Pins reserved by ISO, not for national use.  
Subscripts indicate pins to form pairs.

## RTTY Control Sequences (from CCITT Recommendation S.4)

Sequence	Meaning
ZCZC	start of message
NNNN	end of message
CCCC	enable remote reperforator (or other device)
SSSS	enable remote terminal
FFFF	disable remote reperforator
KKKK	ready for test
KLKL	enable remote reader
XXXXX	error signal

This chart shows CATV and broadcast channels used in the United States and their relationship to the harmonics of MF, HF, VHF and UHF amateur bands.

The FCC specifies that the spurious signals generated by transmitting equipment must be reduced well below the level of the fundamental. This graph illustrates exactly how far the spurious components must be reduced. This applies to amateur transmitters operating below 30 MHz.

This graph illustrates to what level spurious-output energy must be reduced for equipment designed to operate in the 30- to 225-MHz range.

# Frequency Allocation Chart

## 160 METERS

## 80 METERS

5167.5 kHz (SSB only): Alaska emergency use only.

## 40 METERS

\* Phone operation is allowed on 7075–7100 kHz in Puerto Rico, US Virgin islands and areas of the Caribbean south of 20 degrees north latitude; and in Hawaii and areas near ITU Region 3, including Alaska.

## 30 METERS

Maximum power on 30 meters is 200 watts PEP output. Amateurs must avoid interference to the fixed service outside the US.

## 20 METERS

## 17 METERS

## 15 METERS

## 12 METERS

## 10 METERS

Novices and Technicians are limited to 200 watts PEP output on 10 meters.

## 6 METERS

## 2 METERS

## 1.25 METERS

Novices are limited to 25 watts PEP output from 222 to 225 MHz.

## 70 CENTIMETERS \*\*

## 33 CENTIMETERS \*\*

## 23 CENTIMETERS \*\*

Novices are limited to 5 watts PEP output from 1270 to 1295 MHz.

# US AMATEUR BANDS

December 20, 1994

## US AMATEUR POWER LIMITS

At all times, transmitter power should be kept down to that necessary to carry out the desired communications. Power is rated in watts PEP output. Unless otherwise stated, the maximum power output is 1500 W. Power for all license classes is limited to 200 W in the 10,100–10,150 kHz band and in all Novice subbands below 28,100 kHz. Novices and Technicians are restricted to 200 W in the 28,100–28,500 kHz subbands. In addition, Novices are restricted to 25 W in the 222–225 MHz band and 5 W in the 1270–1295 MHz subband.

Operators with Technician class licenses and above may operate on all bands above 50 MHz. For more detailed information see The FCC Rule Book.

## KEY

- = CW, RTTY and data
- = CW, RTTY, data, MCW, test, phone and image
- = CW, phone and image
- = CW and SSB
- = CW, RTTY, data, phone, and image
- = CW only

E = EXTRA CLASS  
A = ADVANCED  
G = GENERAL  
T+ = TECHNICIAN PLUS  
T = TECHNICIAN  
N = NOVICE

\*\* Geographical and power restrictions apply to these bands. See The FCC Rule Book for more information about your area.

## Above 23 Centimeters:

All licensees except Novices are authorized all modes on the following frequencies:

2300–2310 MHz  
2390–2450 MHz  
3300–3500 MHz  
5650–5925 MHz  
10.0–10.5 GHz  
24.0–24.25 GHz  
47.0–47.2 GHz  
75.5–81.0 GHz  
119.98–120.02 GHz  
142–149 GHz  
241–250 GHz  
All above 300 GHz

For band plans and sharing arrangements, see The ARRL Operating Manual or The FCC Rule Book.

Voluntary band plans result from mutual agreement among amateurs. They add to, and are subject to, frequency allocations and subbands defined by FCC regulations (see 30.55).

#### Notes

†Establish contact on voice or CW first, then move off frequency to send images. A "gentlemen's agreement" calls for SSTV operation as close to the calling frequencies as possible.

†† Always establish voice or CW contact before sending fax.

†††Automatic message forwarding: Int - Intercontinental; NA = North America

(b) = beacons

(b<sup>+</sup>) Domestically, beacons can be operating in this segment. Internationally, beacons can be found in the 28.190-28.225 segment.

## VHF/UHF/EFH Calling Frequencies

Band (MHz)	Calling Frequency
50	50.125 SSB 50.620 digital (packet) 52.525 National FM simplex frequency
144	144.010 EME 144.100, 144.110 CW 144.200 SSB 146.520 National FM simplex frequency
222	222.100 CW/SSB 223.500 National FM simplex frequency
432	432.010 EME 432.100 CW/SSB 446.000 National FM simplex frequency
902	902.100 CW,SSB 903.1 Alternate CW, SSB 906.500 National FM simplex frequency
1296	1294.500 National FM simplex frequency 1296.100 CW/SSB
2304	2304.1
10000	10368.1

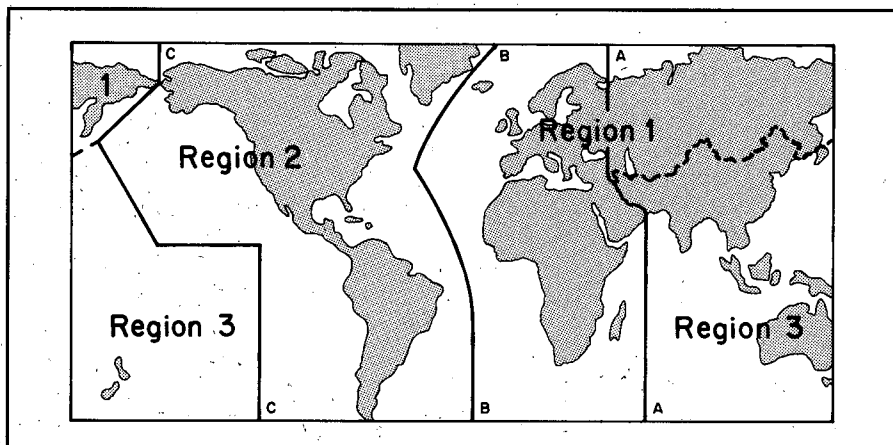

## VHF/UHF Activity Nights

Some areas do not have enough VHF/UHF activity to support contacts at all times. This schedule is intended to help VHF/UHF operators make contact. This is only a starting point; check with others in your area to see if local hams have a different schedule:

Band (MHz)	Day	Local Time
50	Sunday	6 PM
144	Monday	7 PM
222	Tuesday	8 PM
432	Wednesday	9 PM
902	Friday	9 PM
1296	Thursday	10 PM

The ITU divides the world into three regions. Geographic details appear in *The FCC Rule Book* and *The ARRL Operating Manual*.

## DX Operating Code

### *For W/VE Amateurs*

Some amateur DXers have caused considerable confusion and interference in their efforts to work DX stations. The points below, if observed by all W/VE amateurs, will help make DX more enjoyable for all.

- 1) Call DX only after he calls CQ, QXZ? or signs SK, or voice equivalents thereof. Make your calls short.
- 2) Do not call a DX station:
  - a) On the frequency of the station he is calling until you are sure the QSO is over (SK).
  - b) Because you hear someone else calling him.
  - c) When he signs KN, AR or CL.
  - d) Exactly on his frequency.
  - e) After he calls a directional CQ, unless of course you are in the right direction or area.
- 3) Keep within frequency band limits. Some DX stations can get away with working outside, but you cannot.
- 4) Observe calling instructions given by DX stations. Example: 15u means "call 15 kHz up from my frequency." 15d means down, etc.
- 5) Give honest reports. Many DX stations depend on W/VE reports for adjustment of station and equipment.
- 6) Keep your signal clean. Key clicks, ripple, feedback or splatter gives you a bad reputation and may get you a citation from FCC.
- 7) Listen and call the station you want. Calling CQ DX is not the best assurance that the rare DX will reply.
- 8) When there are several W or VE stations waiting, avoid asking DX to "listen for a friend." Also avoid engaging him in a ragchew against his wishes.

### *For Overseas Amateurs*

To all overseas amateur stations:

In their eagerness to work you, many W and VE amateurs resort to practices that cause confusion and QRM. Most of this is good-intentioned but ill-advised; some of it is intentional and selfish. The key to the cessation of unethical DX operating practices is in your hands. We believe that your adoption of certain operating habits will increase your enjoyment of Amateur Radio and that of amateurs on this side who are eager to work you. We recommend your adoption of the following principles:

- 1) Do not answer calls on your own frequency.
- 2) Answer calls from W/VE stations only when their signals are of good quality.
- 3) Refuse to answer calls from other stations when you are already in contact with someone, and do not acknowledge calls from amateurs who indicate they wish to be "next."
- 4) Give everybody a break. When many W/VE amateurs are patiently and quietly waiting to work you, avoid complying with requests to "listen for a friend."
- 5) Tell listeners where to call you by indicating how many kilohertz up (U) or down (D) from your frequency you are listening.
- 6) Use the ARRL-recommended ending signals, especially KN to indicate to impatient listeners the status of the QSO. KN means "Go ahead (specific station); all others keep out."
- 7) Let it be known that you avoid working amateurs who are constant violators of these principles.

## W1AW schedule

Pacific	Mtn	Cent	East	Sun	Mon	Tue	Wed	Thu	Fri	Sat
6 am	7 am	8 am	9 am			Fast Code	Slow Code	Fast Code	Slow Code	
7 am	8 am	9 am	10 am			Code Bulletin				
8 am	9 am	10 am	11 am			Teleprinter Bulletin				
9 am	10 am	11 am	noon			Visiting Operator Time				
10 am	11 am	noon	1 pm							
11 am	noon	1 pm	2 pm							
noon	1 pm	2 pm	3 pm							
1 pm	2 pm	3 pm	4 pm	Slow Code	Fast Code	Slow Code	Fast Code	Slow Code	Fast Code	Slow Code
2 pm	3 pm	4 pm	5 pm	Code Bulletin						
3 pm	4 pm	5 pm	6 pm	Teleprinter Bulletin						
4 pm	5 pm	6 pm	7 pm	Fast Code	Slow Code	Fast Code	Slow Code	Fast Code	Slow Code	Fast Code
5 pm	6 pm	7 pm	8 pm	Code Bulletin						
6 pm	7 pm	8 pm	9 pm	Teleprinter Bulletin						
6 <sup>45</sup> pm	7 <sup>45</sup> pm	8 <sup>45</sup> pm	9 <sup>45</sup> pm	Voice Bulletin						
7 pm	8 pm	9 pm	10 pm	Slow Code	Fast Code	Slow Code	Fast Code	Slow Code	Fast Code	Slow Code
8 pm	9 pm	10 pm	11 pm	Code Bulletin						
9 pm	10 pm	11 pm	Mdnte	Teleprinter Bulletin						
9 <sup>45</sup> pm	10 <sup>45</sup> pm	11 <sup>45</sup> pm	12 <sup>45</sup> am	Voice Bulletin						

Note: W1AW's schedule is at the same local time throughout the year. The schedule according to your local time will change if your local time does not have seasonal adjustments that are made at the same time as North American time changes between standard time and daylight time. From the first Sunday in April to the last Sunday in October, UTC = Eastern Time + 4 hours. For the rest of the year, UTC = Eastern Time + 5 hours.

### ❑ Morse code transmissions:

Frequencies are 1.818, 3.5815, 7.0475, 14.0475, 18.0975, 21.0675, 28.0675 and 147.555 MHz.

Slow Code = practice sent at 5, 7<sup>1/2</sup>, 10, 13 and 15 wpm.

Fast Code = practice sent at 35, 30, 25, 20, 15, 13 and 10 wpm.

Code practice text is from the pages of *QST*. The source is given at the beginning of each practice session and alternate speeds within each session. For example, "Text is from July 1992 *QST*, pages 9 and 81," indicates that the plain text is from the article on page 9 and mixed number/letter groups are from page 81.

Code bulletins are sent at 18 wpm.

### ❑ Teleprinter transmissions:

Frequencies are 3.625, 7.095, 14.095, 18.1025, 21.095, 28.095 and 147.555 MHz.

Bulletins are sent at 45.45-baud Baudot and 100-baud AMTOR, FEC Mode B.

110-baud ASCII will be sent only as time allows.

On Tuesdays and Saturdays at 6:30 PM Eastern Time, Keplerian elements for many amateur satellites are sent on the regular teleprinter frequencies.

### ❑ Voice transmissions:

Frequencies are 1.855, 3.99, 7.29, 14.29, 18.16, 21.39, 28.59 and 147.555 MHz.

### ❑ Miscellanea:

On Fridays, UTC, a DX bulletin replaces the regular bulletins.

W1AW is open to visitors during normal operating hours: from 1 PM until 1 AM on Mondays, 9 AM until 1 AM Tuesday through Friday, from 1 PM to 1 AM on Saturdays, and from 3:30 PM to 1 AM on Sundays. FCC licensed amateurs may operate the station from 1 to 4 PM Monday through Saturday. Be sure to bring your current FCC amateur license or a photocopy.

In a communications emergency, monitor W1AW for special bulletins as follows: voice on the hour, teleprinter at 15 minutes past the hour, and CW on the half hour.

Headquarters and W1AW are closed on New Year's Day, President's Day, Good Friday, Memorial Day, Independence Day, Labor Day, Thanksgiving and the following Friday, and Christmas Day. On the first Thursday of September, Headquarters and W1AW will be closed during the afternoon.

## ARRL Procedural Signals (Prosigns)

In general, the CW prosigns are used on all data modes as well, although word abbreviations may be spelled out. That is, "CLEAR" might be used rather than "CL" on radioteletype. Additional radioteletype conventions appear at the end of the table.

### Situation

check for a clear frequency  
seek contact with any station  
after call to a specific named station or to indicate the end of a message  
invite any station to transmit  
invite a specific named station to transmit  
invite receiving station to transmit  
all received correctly  
please stand by  
end of contact (sent before call sign)  
going off the air

CW	Voice
QRL?	Is the frequency in use?
CQ	CQ
AR	over, end of message
K	go
KN	go only
BK	back to you
R	received
AS	wait, stand by
SK	clear
CL	closing station

### Additional RTTY prosigns

SK QRZ—Ending contact, but listening on frequency.  
SK KN—Ending contact, but listening for one last transmission from the other station.  
SK SZ—Signing off and listening on the frequency for any other calls.

## Q Signals

These Q signals most often need to be expressed with brevity and clarity in amateur work. (Q abbreviations take the form of questions only when each is sent followed by a question mark.)

QRA	What is the name of your station? The name of your station is _____.	QRX	When will you call me again? I will call you again at _____ hours (on _____ kHz).
QRG	Will you tell me my exact frequency (or that of _____)? Your exact frequency (or that of _____) is _____ kHz.	QRY	What is my turn? Your turn is numbered _____
QRH	Does my frequency vary? Your frequency varies.	QRZ	Who is calling me? You are being called by _____ (on _____ kHz).
QRI	How is the tone of my transmission? The tone of your transmission is _____ (1. Good; 2. Variable; 3. Bad).	QSA	What is the strength of my signals (or those of _____)? The strength of your signals (or those of _____) is _____ (1. Scarcely perceptible; 2. Weak; 3. Fairly good; 4. Good; 5. Very good).
QRJ	Are you receiving me badly? I cannot receive you. Your signals are too weak.	QSB	Are my signals fading? Your signals are fading.
QRK	What is the intelligibility of my signals (or those of _____)? The intelligibility of your signals (or those of _____) is _____ (1. Bad; 2. Poor; 3. Fair; 4. Good; 5. Excellent).	QSD	Is my keying defective? Your keying is defective.
QRL	Are you busy? I am busy (or I am busy with _____). Please do not interfere.	QSG	Shall I send _____ messages at a time? Send _____ messages at a time.
QRM	Is my transmission being interfered with? Your transmission is being interfered with (1. Nil; 2. Slightly; 3. Moderately; 4. Severely; 5. Extremely.)	QSK	Can you hear me between your signals and if so can I break in on your transmission? I can hear you between my signals; break in on my transmission.
QRN	Are you troubled by static? I am troubled by static _____ (1-5 as under QRM).	QSL	Can you acknowledge receipt? I am acknowledging receipt.
QRO	Shall I increase power? Increase power.	QSM	Shall I repeat the last message which I sent you, or some previous message? Repeat the last message which you sent me [or message(s) number(s) _____].
QRP	Shall I decrease power? Decrease power.	QSN	Did you hear me (or _____) on _____ kHz? I did hear you (or _____) on _____ kHz.
QRQ	Shall I send faster? Send faster (_____ WPM).	QSO	Can you communicate with _____ direct or by relay? I can communicate with _____ direct (or by relay through _____).
QRS	Shall I send more slowly? Send more slowly (_____ WPM).	QSP	Will you relay to _____? I will relay to _____
QRT	Shall I stop sending? Stop sending.	QST	General call preceding a message addressed to all amateurs and ARRL members. This is in effect "CQ ARRL."
QRU	Have you anything for me? I have nothing for you.	QSU	Shall I send or reply on this frequency (or on _____ kHz)? Send or reply on this frequency (or _____ kHz).
QRV	Are you ready? I am ready.		
QRW	Shall I inform _____ that you are calling on _____ kHz? Please inform _____ that I am calling on _____ kHz.		

## The RST System

### READABILITY

- 1 — Unreadable.
- 2 — Barely readable, occasional words distinguishable.
- 3 — Readable with considerable difficulty.
- 4 — Readable with practically no difficulty.
- 5 — Perfectly readable.

### SIGNAL STRENGTH

- 1 — Faint signals, barely perceptible.
- 2 — Very weak signals.
- 3 — Weak signals.
- 4 — Fair signals.
- 5 — Fairly good signals.
- 6 — Good signals.
- 7 — Moderately strong signals.
- 8 — Strong signals.
- 9 — Extremely strong signals.

### TONE

- 1 — Sixty-cycle ac or less, very rough and broad.
- 2 — Very rough ac, very harsh and broad.
- 3 — Rough ac tone, rectified but not filtered.
- 4 — Rough note, some trace of filtering.
- 5 — Filtered rectified ac but strongly ripple-modulated.
- 6 — Filtered tone, definite trace of ripple modulation.
- 7 — Near pure tone, trace of ripple modulation.
- 8 — Near perfect tone, slight trace of modulation.
- 9 — Perfect tone, no trace of ripple or modulation of any kind.

If the signal has the characteristic steadiness of crystal control, add the letter X to the RST report. If there is a chirp, add the letter C. Similarly for a click, add K. (See FCC Regulations §97.307, Emissions Standards.) The above reporting system is used on both CW and voice; leave out the "tone" report on voice.

QSV Shall I send a series of Vs on this frequency (or on \_\_\_\_\_ kHz)? Send a series of Vs on this frequency (or on \_\_\_\_\_ kHz).

QSW Will you send on this frequency (or on \_\_\_\_\_ kHz)? I am going to send on this frequency (or on \_\_\_\_\_ kHz).

QSX Will you listen to \_\_\_\_\_ on \_\_\_\_\_ kHz? I am listening to \_\_\_\_\_ on \_\_\_\_\_ kHz.

QSY Shall I change to transmission on another frequency? Change to transmission on another frequency (or on \_\_\_\_\_ kHz).

QSZ Shall I send each word or group more than once? Send each word or group twice (or \_\_\_\_\_ times).

QTA Shall I cancel message number \_\_\_\_\_? Cancel message number \_\_\_\_\_.

QTB Do you agree with my counting of words? I do not agree with your counting words. I will repeat the first letter or digit of each word or group.

QTC How many messages have you to send? I have \_\_\_\_\_ messages for you (or for \_\_\_\_\_).

QTH What is your location? My location is \_\_\_\_\_.

QTR What is the correct time? The correct time is \_\_\_\_\_.

QTV Shall I stand guard for you? Stand guard for me.

QTX Will you keep your station open for further communication with me? Keep your station open for me.

QUA Have you news of \_\_\_\_\_? I have news of \_\_\_\_\_.

### ARRL QN Signals

QNA\* Answer in prearranged order.

QNB Act as relay between \_\_\_\_\_ and \_\_\_\_\_.

QNC All net stations copy. I have a message for all net stations.

QND\* Net is Directed (Controlled by net control station.)

QNE\* Entire net stand by.

QNF Net is Free (not controlled).

QNG Take over as net control station

QNH Your net frequency is High.

QNI Net stations report in. I am reporting into the net. (Follow with a list of traffic or QRU.)

QNJ Can you copy me?

QNK\* Transmit messages for \_\_\_\_\_ to \_\_\_\_\_.

QNL Your net frequency is Low.

QNM\* You are QRMing the net. Stand by.

QNN Net control station is \_\_\_\_\_. What station has net control?

QNO Station is leaving the net.

QNP Unable to copy you. Unable to copy \_\_\_\_\_.

QNQ\* Move frequency to \_\_\_\_\_ and wait for \_\_\_\_\_ to finish handling traffic. Then send him traffic for \_\_\_\_\_.

QNR\* Answer \_\_\_\_\_ and Receive traffic.

QNS Following Stations are in the net.\* (follow with list.) Request list of stations in the net.

QNT I request permission to leave the net for \_\_\_\_\_ minutes.

QNU\* The net has traffic for you. Stand by.

QNV\* Establish contact with \_\_\_\_\_ on this frequency. If successful, move to \_\_\_\_\_ and send him traffic for \_\_\_\_\_.

QNW How do I route messages for \_\_\_\_\_?

QNX You are excused from the net.\*

QNY\* Shift to another frequency (or to \_\_\_\_\_ kHz) to clear traffic with \_\_\_\_\_.

QNZ Zero beat your signal with mine.

\* For use only by the Net Control Station.

### Notes on Use of QN Signals

These QN signals are special ARRL signals for use in amateur CW nets *only*. They are not for use in casual amateur conversation. Other meanings that may be used in other services do not apply. Do not use QN signals on phone nets. *Say it with words.* QN signals need not be followed by a question mark, even though the meaning may be interrogatory.

Although abbreviations help to cut down unnecessary transmission, make it a rule not to abbreviate unnecessarily when working an operator of unknown experience.

AA	All after	OC	Old chap
AB	All before	OM	Old man
ABT	About	OP-OPR	Operator
ADR	Address	OT	Old timer; old top
AGN	Again	PBL	Preamble
ANT	Antenna	PSE	Please
BCI	Broadcast interference	PWR	Power
BCL	Broadcast listener	PX	Press
BK	Break; break me; break in	R	Received as transmitted; are
BN	All between; been	RCD	Received
BUG	Semi-automatic key	RCVR (RX)	Receiver
B4	Before	REF	Refer to; referring to; reference
C	Yes	RFI	Radio frequency interference
CFM	Confirm; I confirm	RIG	Station equipment
CK	Check	RPT	Repeat; I repeat; report
CL	I am closing my station; call	RTTY	Radioteletype
CLD-CLG	Called; calling	RX	Receiver
CQ	Calling any station	SASE	Self-addressed, stamped envelope
CUD	Could	SED	Said
CUL	See you later	SIG	Signature; signal
CW	Continuous wave	SINE	Operator's personal initials or nickname
	(i.e., radiotelegraph)	SKED	Schedule
DLD-DLVD	Delivered	SRI	Sorry
DR	Dear	SSB	Single sideband
DX	Distance, foreign countries	SVC	Service; prefix to service message
ES	And, &	T	Zero
FB	Fine business, excellent	TFC	Traffic
FM	Frequency modulation	TMW	Tomorrow
GA	Go ahead (or resume sending)	TNX-TKS	Thanks
GB	Good-by	TT	That
GBA	Give better address	TU	Thank you
GE	Good evening	TVI	Television interference
GG	Going	TX	Transmitter
GM	Good morning	TXT	Text
GN	Good night	UR-URS	Your; you're; yours
GND	Ground	VFO	Variable-frequency oscillator
GUD	Good	VY	Very
HI	The telegraphic laugh; high	WA	Word after
HR	Here, hear	WB	Word before
HV	Have	WD-WDS	Word; words
HW	How	WKD-WKG	Worked; working
LID	A poor operator	WL	Well; will
MA, MILS	Milliamperes	WUD	Would
MSG	Message; prefix to radiogram	WX	Weather
N	No	XCVR	Transceiver
NCS	Net control station	XMTR (TX)	Transmitter
ND	Nothing doing	XTAL	Crystal
NIL	Nothing; I have nothing for you	XYL (YF)	Wife
NM	No more	YL	Young lady
NR	Number	73	Best regards
NW	Now; I resume transmission	88	Love and kisses
OB	Old boy

## ARRL Operating Awards

<i>Award</i>	<i>Qualification</i>
Friendship Award	Contact 26 stations with calls ending A through Z.
Rag Chewer's Club	A single contact 1/2 hour or longer
Worked All States (WAS)	QSLs from all 50 US states (see 30.72)
Worked All Continents (WAC)	QSLs from all six continents
DX Century Club (DXCC)	QSLs from at least 100 different countries
VHF/UHF Century Club (VUCC)	QSLs from many grid squares (see 30.73)
Extra Class Certificate	Hold an Amateur Extra Class license
A-1 Operator Club	Recommendation by two A-1 operators
Code Proficiency	One minute of perfect copy from W1AW qualifying run
Old Timers Club	Held an Amateur Radio license at least 20 years prior
ARRL Membership	ARRL membership for 25, 40, 50, 60 or 70 years

## Operating Aids for Public Service

ARRL HQ makes available the following free operating aids for public service communications:

### Public Service Communications

Manual	FSD-235
ARRL numbered radiograms	FSD-3
Sample emergency plan	FSD-27
ARES registration form	FSD-98
Amateur message form	FSD-218
Emergency Reference information	FSD-255
Field Organization Brochure	FSD-300

This entire Public Service Package can be obtained by sending a large (9 x 12-inch) envelope with First Class postage for 6 ounces

## Principles of Emergency Communication

- 1) *Keep the QRM level down:* Remain silent unless called upon. There are only two reasons to check into an emergency net: (1) You have a bona fide emergency; (2) the Net Control Station (NCS) is requesting help that only you can provide.
- 2) *Monitor established emergency frequencies:* Many areas have established emergency frequencies that should be monitored for possible distress calls.
- 3) *Avoid spreading rumors:* Transmit only facts, not speculation. Do not repeat messages unless so authorized by the originator, and then only *word for word*.
- 4) *Authenticate all messages:* Any messages of an official nature should be written and signed.
- 5) *Strive for efficiency:* You are more effective as part of a team than as a lone individual.
- 6) *Select the mode and band to suit the need:* Advantages of several modes are listed below.
- 7) *Use all communications channels intelligently:* The object is to protect lives and property. Use emergency or normal communications channels where available.
- 8) *Don't broadcast:* Our job is to communicate for, not with, the general public. See §97.113 of *The FCC Rule Book* for details.

### Advantages of Various Amateur Modes for Emergency Communications

#### CW

- 1) Less QRM in most amateur bands.
- 2) Privacy of communications (less easily understood by the public).
- 3) Simpler transmitting equipment.
- 4) Greater accuracy than voice in record communications.
- 5) Longer range for a given transmitter power level.

#### Voice

- 1) More practical for portable and mobile work.
- 2) More widespread availability of operators.
- 3) Faster communication for tactical or "command" purposes.
- 4) More readily appreciated and understood by the public.
- 5) Official-to-official and phone-patch communication.

#### Packet/AMTOR/PacTOR/CLOVER

- 1) Less QRM in most amateur bands.
- 2) Privacy of communications (less easily understood by the public).
- 3) More widespread availability of operators.
- 4) Greater speed and accuracy of record communication than any other modes.

## ARES Personal Checklist

The following represents recommendations of equipment and supplies ARES members should consider having available for use during an emergency or public-service activity.

- 1) ARES Identification Card
- 2) FCC Amateur Radio License
- 3) Radio Gear
  - rig (2 meters)
  - microphone
  - headphones
  - power supply/extra batteries
  - antennas with mounts
  - spare fuses
  - path cords/adapters (BNC to PL259/ RCA phono to PL259)
  - SWR meter
  - extra coax
- 4) Writing Gear
  - pen/pencil/eraser
  - clipboard
  - message forms
  - logbook
  - note paper
- 5) Personal Gear (short duration)
  - snacks
  - liquid refreshments
  - throat lozenges
  - personal medicine
  - aspirin
  - extra pair of prescription glasses
- 6) Personal Gear (72-hour duration)
  - foul-weather gear
  - three-day supply of drinking water
  - cooler with three-day supply of food
  - mess kit with cleaning supplies
  - first-aid kit
  - personal medicine
  - aspirin
  - throat lozenges
  - sleeping bag
  - toilet articles
  - mechanical alarm clock
  - flashlight with batteries/lantern
  - candles
  - waterproof matches
  - extra pair of prescription glasses
- 7) Tool Box (72-hour duration)
  - screwdrivers
  - pliers
  - socket wrenches
  - electrical tape
  - 12/120-V soldering iron
  - solder
  - volt-ohm meter
- 8) Other (72-hour duration)
  - hatchet/ax
  - saw
  - pick
  - shovel
  - siphon
  - jumper cables
  - 3/8-inch rope
  - highway flares
  - extra gasoline and oil

## ARES/RACES

The Amateur Radio Emergency Service (ARES) and the Radio Amateur Civil Emergency Service (RACES) are the umbrella organizations of Amateur Radio public service. ARES is sponsored by ARRL (although ARRL membership is not required for participation) and handles all kinds of public-service activities. RACES is administered by the Federal Emergency Management Agency (FEMA) and operates only for civil preparedness and in times of civil emergency. RACES is activated at the request of a state or federal official.

The ARRL advocates dual membership and cooperative efforts between ARES and RACES whenever possible. RACES rules now make it possible for ARES and RACES to use the same frequencies, so that an ARES group also enrolled as RACES can "switch hats" from ARES to RACES and RACES to ARES as the situation develops. In many areas, however, the two organizations exist separately. Contact local ARRL Leadership Officials to determine the situation in your area.

ARES officials operate under the ARRL Section Manager. Figs A and B show the Section and local ARES structures, respectively.

The Radio Amateur Civil Emergency Service (RACES) comprises certain Amateur Radio operators and stations that are registered with civil defense organizations or licensed as RACES stations by the FCC. RACES frequencies are normally shared with the Amateur Radio Service, but in times of civil emergency and for limited periods of testing and practice RACES operation is limited to the frequencies shown below. During times of official RACES operation, RACES stations may only contact other RACES stations and certain other stations as listed in §97.407(c). Official RACES operation does not allow radio contact with the general amateur population.

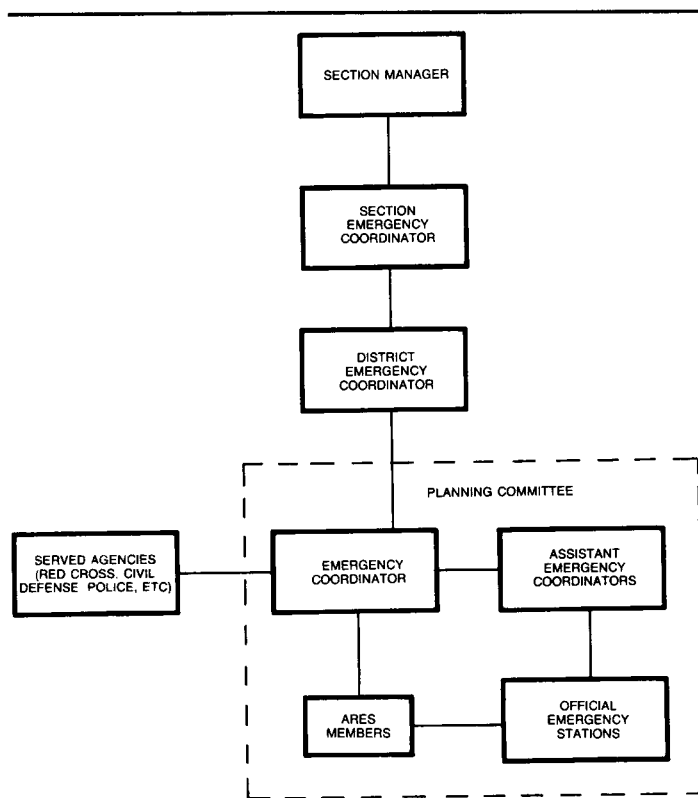

Fig A—Section-level ARES structure.

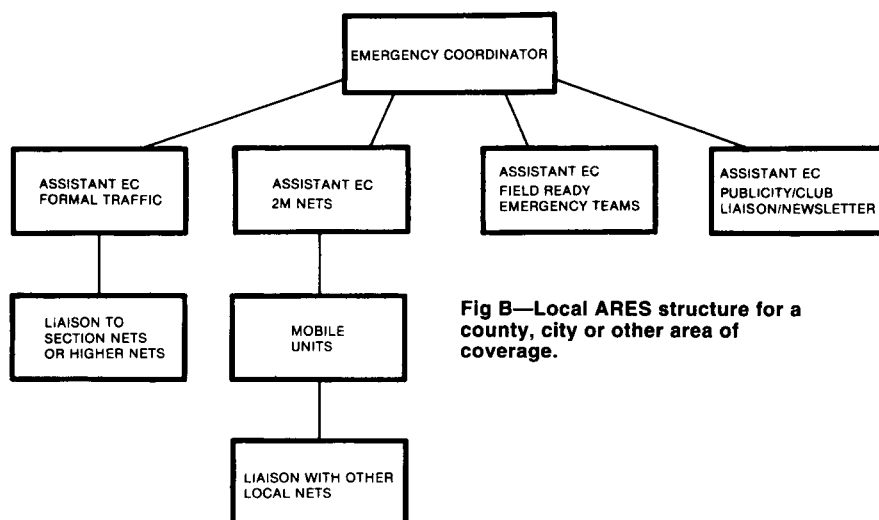

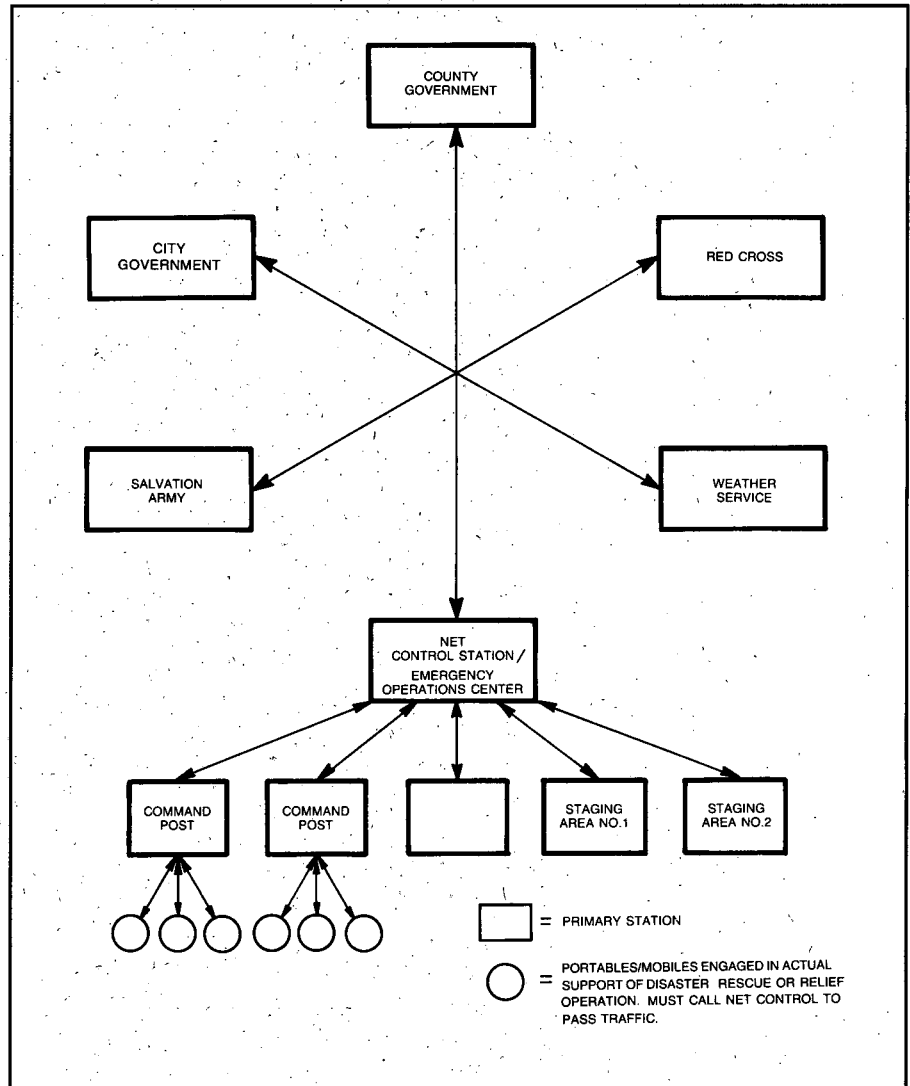

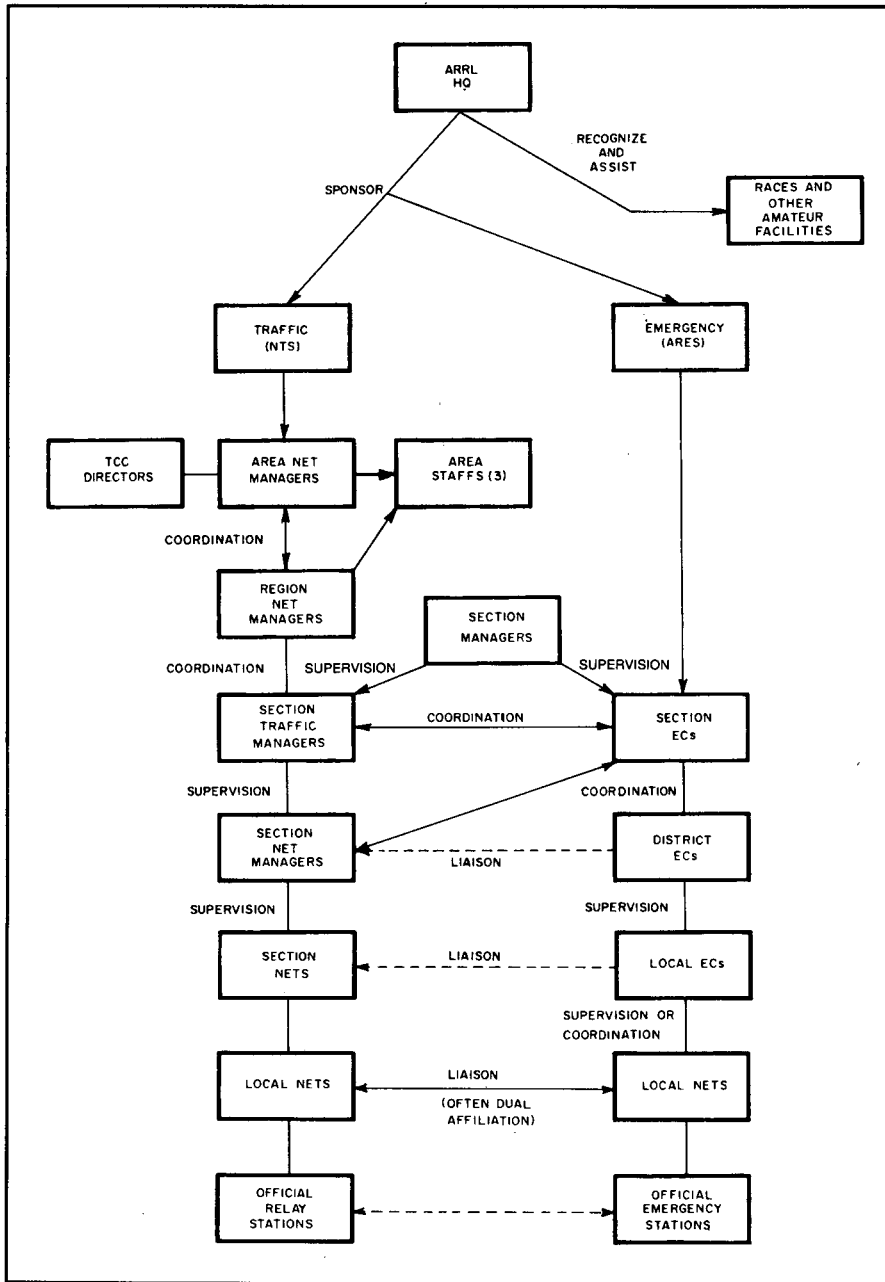

Fig B—Local ARES structure for a county, city or other area of coverage.

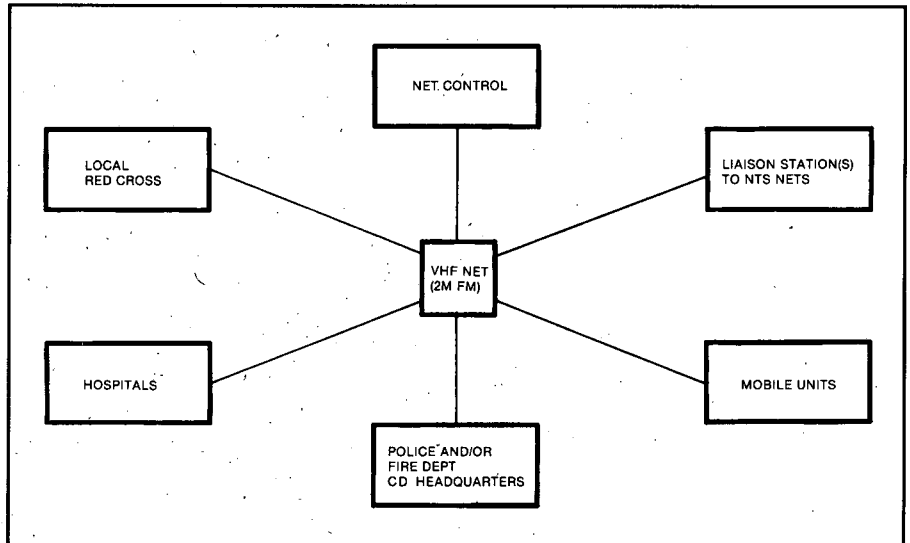

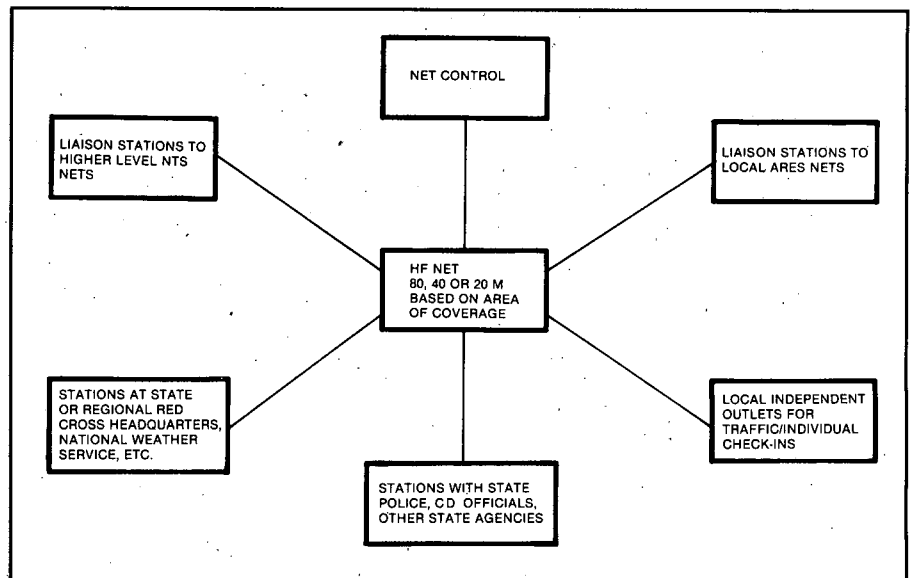

### Dedicated RACES Operating Frequencies

RACES frequencies are shared with amateurs except in certain emergencies. See *The FCC Rule Book* (§97.407) for details of RACES operation.

kHz	MHz	MHz
1800-1825	10.100-10.150	50.350-50.750
1975-2000	14.047-14.053	52.000-54.000
3500-3550	14.220-14.230	144.50-145.71
3930-3980	14.331-14.350	146.00-148.00
3984-4000	21.047-21.053	222.00-225.00
7079-7125	21.228-21.267	420.00-450.00
7245-7255	28.550-28.750	1240.00-1300.00
	29.237-29.273	2390.00-2450.00
		29.450-29.650

**30.81****Typical station deployment for local ARES net coverage in an emergency.****30.82****Typical structure of an HF network for emergency communications.**

# AMATEUR MESSAGE FORM

Every formal radiogram message originated and handled should contain the following component parts in the order given.

## I PREAMBLE

- Number (begin with 1 each month or year)
- Precedence (R, W, P or EMERGENCY)
- Handling Instructions (optional, see text)
- Station of Origin (first amateur handler)
- Check (number of words/groups in text only)
- Place of Origin (not necessarily location of station of origin)
- Time Filed (optional with originating station)
- Date (must agree with date of time filed)

## II ADDRESS (as complete as possible, include zip code and telephone number)

## III TEXT (limit to 25 words or less, if possible)

## IV SIGNATURE

## CW MESSAGE EXAMPLE

I NR 1 R HXG W1AW 8 NEWINGTON CONN 1830Z JULY 1  
 a b c d e f g h  
 II DONALD SMITH AA  
 164 EAST SIXTH AVE AA  
 NORTH RIVER CITY MO 00789 AA  
 733 4968 BT  
 III HAPPY BIRTHDAY X SEE YOU SOON X LOVE BT  
 IV DIANA AR

Note that X, when used in the text as punctuation, counts as a word.

CW: The prosign AA separates the parts of the address. BT separates the address from the text and the text from the signature. AR marks end of message; this is followed by B if there is another message to follow, by N if this is the only or last message. It is customary to copy the preamble, parts of the address, text and signature on separate lines.

RTTY: Same as cw procedure above, except (1) use extra space between parts of address, instead of AA; (2) omit cw procedure sign BT to separate text from address and signature, using line spaces instead; (3) add a CFM line under the signature, consisting of all names, numerals and unusual words in the message in the order transmitted.

PACKET/AMTOR BBS: Same format as shown in the cw message example above, except that the AA and AR prosigns may be omitted. Most amtor and packet BBS software in use today allows formal message traffic to be sent with the "ST" command. Always avoid the use of spectrum-wasting multiple line feeds and indentations.

PHONE: Use *prowords* instead of prosigns, but it is not necessary to name each part of the message as you send it. For example, the above message would be sent on phone as follows: "Number one routine HX Golf W1AW eight Newington Connecticut one eight three zero zulu July one Donald Smith Figures one six four East Sixth Avenue North River City Missouri zero zero seven eight nine Telephone seven three three four nine six eight Break Happy birthday X-ray see you soon X-ray love Break Diana End of Message Over. "End of Message" is followed by "More" if there is another message to follow, "No More" if it is the only or last message. Speak clearly using VOX (or pause frequently on push-to-talk) so that the receiving station can get fills. Spell phonetically all difficult or unusual words—do not spell out common words. Do not use cw abbreviations or Q-signals in phone traffic handling.

## PRECEDENCES

The precedence will follow the message number. For example, on cw 207 R or 207 EMERGENCY. On phone, "Two Zero Seven, Routine (or Emergency)."

**EMERGENCY**—Any message having life and death urgency to any person or group of persons, which is transmitted by Amateur Radio in the absence of regular commercial facilities. This includes official messages of welfare agencies during emergencies requesting supplies, materials or instructions vital to relief of stricken populace in emergency areas. During normal times, it will be *very rare*. On cw, RTTY and other digital modes this designation will always be spelled out. When in doubt, *do not* use it.

**PRIORITY**—Important messages having a specific time limit. Official messages not covered in the Emergency category. Press dispatches and other emergency-related traffic not of the utmost urgency. Notification of death or injury in a disaster area, personal or official. Use the abbreviation P on cw.

**WELFARE**—A message that is either a) an inquiry as to the health and welfare of an individual in the disaster area b) an advisory or reply from the disaster area that indicates all is well should carry this precedence, which is abbreviated W on cw. These messages are handled *after* Emergency and Priority traffic but before Routine.

**ROUTINE**—Most traffic normal times will bear this designation. In disaster situations, traffic labeled Routine (R on cw) should be handled *last*, or not at all when circuits are busy with Emergency, Priority or Welfare traffic.

## Handling Instructions (Optional)

**HXA**—(Followed by number.) Collect landline delivery authorized by addressee within . . . . . miles. (If no number, authorization is unlimited.)

**HXB**—(Followed by number.) Cancel message if not delivered within . . . . . hours of filing time; service originating station.

**HXC**—Report date and time of delivery (TOD) to originating station.

**HXD**—Report to originating station the identity of station from which received, plus date and time. Report identity of station to which relayed, plus date and time, or if delivered report date, time and method of delivery.

**HXE**—Delivering station get reply from addressee, originate message back.

**HXF**—(Followed by number.) Hold delivery until . . . . . (date).

**HXG**—Delivery by mail or landline toll call not required. If toll or other expense involved, cancel message and service originating station.

For further information on traffic handling, consult the Public Service Communications Manual or the ARRL Operating Manual, both published by ARRL.

## A simple NTS formal message.

## Handling Instructions

THIS IS A FORMAL MESSAGE. FORMAL MEANS THAT THE MESSAGE FOLLOWS A PRE-ESTABLISHED FORM OR CONVENTION. A FORMAL MESSAGE CONTAINS ALL THE NECESSARY "RECORDKEEPING" ELEMENTS THAT ARE REQUIRED TO KEEP A HISTORY OF THE MESSAGE AS IT IS SENT THROUGH THE NTS. ALL FORMAL MESSAGES CONSIST OF FOUR PARTS: THE PREAMBLE, THE ADDRESS, THE TEXT AND THE SIGNATURE.

RADIOGRAM									
1 PREAMBLE	NUMBER 3 4 7	PRECEDENCE R	HX E	STN OF ORIGIN K7ABT	CHECK 2 5	PLACE OF ORIGIN PHOENIX AZ	TIME FILED	DATE DEC 4	
2 ADDRESS	TO: ALBERT M COUSINS 337 W 38TH STREET BRIDGEPORT CT 06645 TELEPHONE NO: 203 334 5678								
3 TEXT	DEAR	DAD	ARRIVED	SAFELY	339TH				
	COMPOSITE	BOMB	GROUP	FLAGSTAFF	DECEMBER				
	2ND	X	TELL	SHERRY	IM				
	OK	X	PHONE	602	345				
	9876	SEND	FLAK	JACKET	LOVE				
4 SIGNATURE	BILLY					043	89	9078	

EACH OF THE ELEMENTS OF THE FORMAL MESSAGE HAS CERTAIN FORMAT REQUIREMENTS WHICH MUST BE MET IN ORDER TO AVOID CONFUSION ON THE AIR AS THE MESSAGE IS SENT, AND ALSO TO ASSURE THAT A SENDER-TO-RECEIVER TRACE CAN ALWAYS BE DONE ON THE MESSAGE.

HXA—(Followed by number.) Collect landline delivery authorized by addressee within \_\_\_\_\_ miles. (If no number, authorization is unlimited.)

HXB—(Followed by number.) Cancel messages if not delivered within \_\_\_\_\_ hours of filing time; service originating station.

HXC—Report date and time of delivery (TOD) to originating station.

HXD—Report to originating station the identity of station from which received, plus date and time. Report identity of station to which relayed, plus date and time, or if delivered report date, time and method of delivery.

HXE—Delivering station get reply from addressee, originate message back.

HXF—(Followed by number.) Hold delivery until \_\_\_\_\_ (date).

HXG—Delivery by mail or landline toll call not required. If toll or other expense involved, cancel message and service originating station.

An HX prosign (when used) will be inserted in the message preamble before the station of origin, thus: NR 207 R HXA50 W1AW 12...(etc). If more than one HX prosign is used they can be combined if no numbers are to be inserted; otherwise the HX should be repeated, thus: NR 207 R HXAC W1AW... (etc), but: NR 207 R HXA50 HXC W1AW...(etc). One phone, use phonetics for the letter or letters following the HX, to ensure accuracy.

## ARL Numbered Radiograms

The letters ARL are inserted in the preamble in the check and in the text before spelled out numbers, which represent texts from this list. Note that some ARL texts include insertion of numerals. *Example:* NR 1 R W1AW ARL 5 NEWINGTON CONN DEC 25 DONALD R SMITH AA 164 EAST SIXTH AVE AA NORTH RIVER CITY MO AA PHONE 733 3968 BT ARL FIFTY ARL SIXTY ONE BT DIANA AR.

### Group One—For possible “Relief Emergency” Use

ONE	Everyone safe here. Please don't worry.
TWO	Coming home as soon as possible.
THREE	Am in _____ hospital. Receiving excellent care and recovering fine.
FOUR	Only slight property damage here. Do not be concerned about disaster reports.
FIVE	Am moving to new location. Send no further mail or communication. Will inform you of new address when relocated.
SIX	Will contact you as soon as possible.
SEVEN	Please reply by Amateur Radio through the amateur delivering this message. This is a free public service.
EIGHT	Need additional _____ mobile or portable equipment for immediate emergency use.
NINE	Additional _____ radio operators needed to assist with emergency at this location.
TEN	Please contact _____. Advise to standby and provide further emergency information, instructions or assistance.
ELEVEN	Establish Amateur Radio emergency communications with _____ on _____ MHz.
TWELVE	Anxious to hear from you. No word in some time. Please contact me as soon as possible.
THIRTEEN	Medical emergency situation exists here.
FOURTEEN	Situation here becoming critical. Losses and damage from _____ increasing.
FIFTEEN	Please advise your condition and what help is needed.
SIXTEEN	Property damage very severe in this area.
SEVENTEEN	REACT communications services also available. Establish REACT communications with _____ on channel _____.
EIGHTEEN	Please contact me as soon as possible at _____.
NINETEEN	Request health and welfare report on _____. (State name, address and telephone number.)
TWENTY	Temporarily stranded. Will need some assistance. Please contact me at _____.
TWENTY ONE	Search and Rescue assistance is needed by local authorities here. Advise availability.
TWENTY TWO	Need accurate information on the extent and type of conditions now existing at your location. Please furnish this information and reply without delay.
TWENTY THREE	Report at once the accessibility and best way to reach your location.
TWENTY FOUR	Evacuation of residents from this area urgently needed. Advise plans for help.
TWENTY FIVE	Furnish as soon as possible the weather conditions at your location.
TWENTY SIX	Help and care for evacuation of sick and injured from this location needed at once.

Emergency/priority messages originating from official sources must carry the signature of the originating official.

### Group Two—Routine messages

FORTY SIX	Greetings on your birthday and best wishes for many more to come.
FIFTY	Greetings by Amateur Radio.
FIFTY ONE	Greetings by Amateur Radio. This messages is sent as a free public service by ham radio operators here at _____. Am having a wonderful time.
FIFTY TWO	Really enjoyed being with you. Looking forward to getting together again.
FIFTY THREE	Received your _____. It's appreciated; many thanks.
FIFTY FOUR	Many thanks for your good wishes.
FIFTY FIVE	Good news is always welcome. Very delighted to hear about yours.
FIFTY SIX	Congratulations on your _____, a most worthy and deserved achievement.
FIFTY SEVEN	Wish we could be together.
FIFTY EIGHT	Have a wonderful time. Let us know when you return.
FIFTY NINE	Congratulations on the new arrival. Hope mother and child are well.
*SIXTY	Wishing you the best of everything on _____.
SIXTY ONE	Wishing you a very merry Christmas and a happy New Year.
*SIXTY TWO	Greetings and best wishes to you for a pleasant _____ holiday season.
SIXTY THREE	Victory or defeat, our best wishes are with you. Hope you win.
SIXTY FOUR	Arrived safely at _____.
SIXTY FIVE	Arriving _____ on _____. Please arrange to meet me there.
SIXTY SIX	DX QSLs are on hand for you at the _____ QSL Bureau. Send _____ self-addressed envelopes.
SIXTY SEVEN	Your message number _____ undeliverable because of _____. Please advise.
SIXTY EIGHT	Sorry to hear you are ill. Best wishes for a speedy recovery.
SIXTY NINE	Welcome to the _____. We are glad to have you with us and hope you will enjoy the fun and fellowship of the organization.

\* Can be used for all holidays.

Note: ARL numbers should be spelled out at all times.

Traffic handlers don't have to dine out to fight over the check! Even good ops find much confusion when counting up the text of a message. You can eliminate some of this confusion by remembering these basic rules:

- 1) Punctuation ("X-rays," "Querys") count separately as a word.
- 2) Mixed letter-number groups (1700Z, for instance) count as one word.
- 3) Initial or number groups count as one word if sent together, two if sent separately.
- 4) The signature does not count as part of the text, but any closing lines, such as "Love" or "Best wishes" do.

Here are some examples:

- Charles J McClain—3 words
- W B Stewart—3 words
- St Louis—2 words
- 3 PM—2 words
- SASE—1 word
- ARL FORTY SIX—3 words
- 2N1601—1 word
- Seventy three—2 words
- 73—1 word

Telephone numbers count as 3 words (area code, prefix, number), and ZIP codes count as one. ZIP + 4 codes count as two words. Canadian postal codes count as two words (first three characters, last three characters.)

Although it is improper to change the text of a message, you may change the check. Always do this by following the original check with a slash bar, then the corrected check. On phone, use the words "corrected to."

As a net operator, you have a duty to be self-disciplined. A net is only as good as its worst operator. You can be an exemplary net operator by following a few easy guidelines.

1) *Zero beat the NCS.* The NCS doesn't have time to chase all over the band for you. Make sure you're on frequency, and you will never be known at the annual net picnic as "old so-and-so who's always off frequency."

2) *Don't be late.* There's no such thing as "fashionably late" on a net. Liaison stations are on a tight timetable. Don't hold them up by checking in 10 minutes late with three pieces of traffic.

3) *Speak only when spoken to by the NCS.* Unless it is a bona fide emergency situation, you don't need to "help" the NCS unless asked. If you need to contact the NCS, make it brief. Resist the urge to help clear the frequency for the NCS or to "advise" the NCS. The NCS, not you, is boss.

4) Unless otherwise instructed by the NCS, *transmit only* to the NCS. Side comments to another station in the net are out of order.

5) *Stay until you are excused.* If the NCS calls you and you don't respond because you're getting a "cold one" from the fridge, the NCS may assume you've left the net, and net business may be stymied. If you need to leave the net prematurely, contact the NCS and simply ask to be excused (QNX PSE on CW).

6) *Be brief when transmitting to the NCS.* A simple "yes" (C) or "no" (N) will usually suffice. Shaggy dog tales only waste valuable net time.

7) *Know how the net runs.* The NCS doesn't have time to explain procedure to you. After you have been on the net for a while, you should already know these things.

## Tips on Handling NTS Traffic by Packet Radio

### Listing Messages

\* After logging on to your local NTS-supported bulletin board, type the command LT, meaning List Traffic. The BBS will sort and display an index of all NTSXX traffic awaiting delivery.

### Receiving Messages

\* To take a message off the Bulletin Board for telephone delivery to the third party, or for relay to a NTS Local or Section Net, type the R command, meaning Read Traffic, and the message number. R 188 will cause the BBS to find the BBS message number 188. This RADIOGRAM will look like any other, with preamble, address, text and signature; only some additional packet-related message header information is added. This information includes the routing path of the message for auditing purposes; e.g., to discern any excessive delays in the system.

\* After the message is saved to the printer or disk, the message should be KILLED by using the KT command, meaning Kill Traffic, and the message number. In the above case, at the BBS prompt, type KT 188. This prevents the message from being delivered twice. Some of the newer BBS software requires use of K rather than KT.

\* At the time the message is killed, many BBS's will automatically send a message back to the station in the FROM field with information on who took the traffic, and when it was taken!

### Delivering or Relaying A Message

\* A downloaded RADIOGRAM should, of course, be handled expeditiously in the traditional way: telephone delivery, or relay to another net.

### Sending Messages

\* To send a RADIOGRAM, use the ST command, meaning Send Traffic. The BBS will prompt you for the NTS routing (06111 @ NTSCT, for example), the message title which should contain the city in the address of the RADIOGRAM (QTC 1 Dayton), and the text of the message in RADIOGRAM format. The BBS, usually within the hour, will check its outgoing mailpouch, find the NTSCT message and automatically forward it to the next packet station in line to the NTSCT node. Note: Some states have more than one ARRL Section. If you do not know the destination ARRL

Section ("Is San Angelo in the ARRL North, South or West Texas Section?"), then simply use the state designator NTSTX.

\* Note: While NTS/packet radio message forwarding is evolving rapidly, there are still some gaps. When uploading an NTS message destined for a distant state, use handling instruction "HXC" to ask the delivering station to report back to you the date and time of delivery.

\* Unbundle your messages please: one NTS message per BBS message. Please remember that traffic eventually will have to be broken down to the individual addressee somewhere down the line for ultimate delivery. When you place two or more NTS messages destined for different addressees within one packet message, eventually the routing will require the messages to be broken up by either the BBS SYSOP or the relay station, placing an additional, unreasonable burden on them. Therefore it is good practice for the originator to expend the extra word processing in the first place and create individual messages per city regardless if there are common parts of other messages. This means that book messages are not suitable in packet at this time unless they are going to the same city. Bottom line: Messages should be sent unbundled. (Txn NI6A for this tip)

### We Want You!

Local and Section BBS's need to be checked daily for NTS traffic. SYSOPs and STMs can't do it alone. They need your help to clear NTS RADIOGRAMS every day, seven days a week, for delivery and relay. If you are a traffic handler/packeteer, contact your Section Traffic Manager or Section Manager for information on existing NTS/packet procedures in your Section.

If you are a packeteer, and know nothing of NTS traffic handling, contact ARRL HQ, your Section Manager or Section Traffic Manager for information on how you can put your packet radio gear to use in serving the public in routine times, but especially in times of emergency!

And, if you enjoy phone/CW traffic handling, but aren't on packet yet, discover the incredible speed and accuracy of packet radio traffic handling. You probably already have a small computer and 2-meter rig; all you need is a packet radio "black box" to connect between your 2-meter rig and computer. For more information on packet radio, see *Your Packet Companion* or *Your Gateway to Packet Radio*, both published by ARRL.

About the

# American Radio Relay League

---

The seed for Amateur Radio was planted in the 1890s, when Guglielmo Marconi began his experiments in wireless telegraphy. Soon he was joined by dozens, then hundreds, of others who were enthusiastic about sending and receiving messages through the air—some with a commercial interest, but others solely out of a love for this new communications medium. The United States government began licensing Amateur Radio operators in 1912.

By 1914, there were thousands of Amateur Radio operators—hams—in the United States. Hiram Percy Maxim, a leading Hartford, Connecticut, inventor and industrialist saw the need for an organization to band together this fledgling group of radio experimenters. In May 1914 he founded the American Radio Relay League (ARRL) to meet that need.

Today ARRL, with more than 170,000 members, is the largest organization of radio amateurs in the United States. The League is a not-for-profit organization that:

- promotes interest in Amateur Radio communications and experimentation
- represents US radio amateurs in legislative matters, and
- maintains fraternalism and a high standard of conduct among

Amateur Radio operators.

At League headquarters in the Hartford suburb of Newington, the staff helps serve the needs of members. ARRL is also International Secretariat for the International Amateur Radio Union, which is made up of similar societies in more than 100 countries around the world.

ARRL publishes the monthly journal *QST*, as well as newsletters and many publications covering all aspects of Amateur Radio. Its headquarters station, W1AW, transmits bulletins of interest to radio amateurs and Morse code practice sessions.

The League also coordinates an extensive field organization, which includes volunteers who provide technical information for radio amateurs and public-service activities. ARRL also represents US amateurs with the Federal Communications Commission and other government agencies in the US and abroad.

Membership in ARRL means much more than receiving *QST* each month. In addition to the services already described, ARRL offers membership services on a personal level, such as the ARRL Volunteer Examiner Coordinator Program and a QSL bureau.

Full ARRL membership (available only to licensed radio amateurs) gives you a voice in how the affairs of the organization are governed. League policy is set by a Board of Directors (one from each of 15 Divisions). Each year, half of the ARRL Board of Directors stands for election by the full members they represent. The day-to-day operation of ARRL HQ is managed by an Executive Vice President and a Chief Financial Officer.

No matter what aspect of Amateur Radio attracts you, ARRL membership is relevant and important. There would be no Amateur Radio as we know it today were it not for the ARRL. We would be happy to welcome you as a member! (An Amateur Radio license is not required for Associate Membership.) For more information about ARRL and answers to any questions you may have about Amateur Radio, write or call:

ARRL Educational Activities Dept  
225 Main Street  
Newington CT 06111-1494  
(860) 594-0200  
Prospective new amateurs call:  
800-32-NEW HAM (800-326-3942)

# Index

Editor's Note: Except for commonly used phrases and abbreviations, topics are indexed by their noun names. Many topics are also cross-indexed, especially when noun modifiers appear (such as "Voltage, back" and "Back voltage"). Numerous terms and abbreviations pertaining to Amateur Radio but not contained in the index may be found in the glossaries indexed herein. The letters "ff" after a page number indicate coverage of the indexed topic on succeeding pages.

 Abbreviations for CW Work: ..... 30.56  
 Abbreviations List: ..... 30.6  
 Absorption: ..... 21.2, 21.11  
 AC:  
   "ac/dc" circuitry: ..... 27.1  
   AC/RF sources: ..... 14.1ff  
   Average vs peak: ..... 26.9  
   Bridges: ..... 26.13  
   In capacitance: ..... 6.13  
   In inductors: ..... 6.20  
   Line cords: ..... 9.9  
   Line filter: ..... 28.6  
   Measurements: ..... 26.8, 26.9  
   Power sources: ..... 11.2, 22.15  
   Probes: ..... 26.9  
   Ripple, troubleshooting: ..... 27.13  
   Waveforms: ..... 26.9  
 Academy of Model Aeronautics: ..... 12.54  
 Access code: ..... 23.2  
 Accumulator: ..... 7.24  
 Accuracy: ..... 4.4  
 Acid-core solder: ..... 25.3  
 ACSSB (amplitude-companded SSB): 3.8, 12.6  
 Active attenuator for VHF-FM, An: ..... 23.75  
 Active filters: ..... 16.28  
 Active region: ..... 8.21  
 Acute angles: ..... 4.11  
 Acute triangles: ..... 4.13  
 Adder: ..... 15.1ff  
 Addition, in DSP: ..... 18.4  
 Additional loss due to SWR: ..... 19.5  
 Address List, ARRL *Handbook*: ..... 30.9  
 Address register: ..... 7.24  
 Admittance: ..... 6.1, 6.33

Adveective winds: ..... 21.23  
 AE6C Dual-Band Inverted-L antenna: ..... 20.27  
 AF oscillators: ..... 26.19ff  
 AF phasing networks: ..... 12.4  
 AGC: ..... 17.19, 17.22, 17.26, 17.35  
   Audio: ..... 17.46  
   Circuits: ..... 17.28  
   Gain-control chart: ..... 17.27  
   Troubleshooting: ..... 27.14, 27.18, 27.21, 27.22  
 Air capacitors: ..... 10.5  
 Air-core inductors: ..... 6.22  
   Current balun: ..... 19.16  
   RF transformers: ..... 6.46  
 ALC: ..... 12.2, 13.33, 17.46, 17.50, 17.52  
 Algebra: ..... 4.1  
   Complex: ..... 4.15  
 Algonquin Radio Observatory: ..... 21.10  
 Alias signals: ..... 18.3  
 Alignment, troubleshooting: .. 27.12, 27.18, 27.20  
 Allocation of International Call Signs: ..... 30.50  
 Aloha protocol: ..... 12.22  
 Alternating current (Also see AC): ..... 5.1, 6.1  
 Alternator: ..... 6.2  
 ALU: ..... 7.23  
 Aluminum:  
   Alloy characteristics: ..... 24.9  
   Finishing: ..... 25.24  
   Standard Tubing Sizes: ..... 30.35  
   Tubing: ..... 20.35  
 AM: ..... 3.2, 8.4, 12.2  
   Band: ..... 15.7  
   Compatible (CAM): ..... 15.7  
   Demodulation: ..... 15.8ff  
   Demodulation (DSP): ..... 18.14  
   Double-sideband: ..... 15.7  
   Equivalent (AME): ..... 15.7  
   Fax: ..... 12.34  
   For vestigial-sideband, full-carrier: ..... 15.7  
   Independent-sideband (ISB): ..... 15.7  
   Overmodulation: ..... 12.2  
   Single-sideband: ..... 15.7  
   Synchronous detector: ..... 15.32ff  
 Amateur Radio: ..... 1.1ff, 1.10  
   Awards: ..... 1.4  
   Bands, US: ..... 30.47  
   Call signs: ..... 1.3  
   Contests: ..... 1.4  
   Experimentation: ..... 29.2

Getting started in: ..... 1.5  
 Licenses: ..... 1.5  
 Message Form: ..... 30.66  
 Operator: ..... 1.10  
 Technology: ..... 1.5  
 Amateur Radio Service: ..... 1.10, 29.1ff
